LXXVI.—PROGNOSIS IN MIDDLE-EAR

SUPPURATION

MIDDLE-EAR suppuration is met with at all periods of life from earliest infancy to extreme old age. It is responsible not only for an enormous amount of discomfort and suffering, but also for serious disabilities and, in many cases, gives rise to conditions whereby life itself is endangered. It is thus foolish to regard middle-ear suppuration as a trivial ailment, and it was not unusual some years ago, and it is fortunate that in recent years a careful study of the etiology and the natural course of the disease, together with the varieties of treatment and the alterations they have been found to effect, have improved the prognosis immensely in all directions.

In the vast majority of cases the infection reaches the middle ear via the Eustachian tube, although in such things there is reason to believe that the infection is more often blood-borne than in adults. The spread of infection from the pharynx or nasopharynx is usually the sequel of a cold or some more severe infection such as influenza or one of the specific evers. Any unhealthy condition of the nasopharynx, or example adenoids, predisposes to the occurrence, and it has been known to follow plugging of the nasopharynx, or even of the nose after operations, or the entrance of blood or discharges into the Eustachian tube. The entrance of unclean water when diving or swimming under water is also a source of middle-ear suppuration.

Middle-ear suppuration occurs very readily in sucklings and infants as the Eustachian tube is comparatively short, wide, and straight, and in the early months of life the mucous membranes are very prone to infection. That the pharynx is often the site of infection is evident from the frequent association of an enlarged cervical gland and middle-ear suppuration. It is important that small infants should be kept from those suffering from the common cold, as a cold in the head, usually a trivial affair in adults, may be a serious matter in infancy. It would be a counsel of perfection to suggest that all young children suffering from colds should be kept in bed for a day or two, but if it was the rule, not only would the spread of infection be prevented, but the occurrence of middle-ear suppuration would be diminished.

When infection reaches the middle ear and suppuration occurs, the products of inflammation accumulate in the first place in the lower part of the tympanic cavity, the atrium. It will be remembered that the tympanic cavity may be considered as consisting of two parts, the lower or atrium, and the upper or attic. The atrium is a simple four-sided cavity lined by a thin adherent mucosa with very little connective tissue; the Eustachian tube opens into its anterior wall and its external wall is the tympanic membrane or eardrum. The attic, on the other hand, is a complicated cavity, containing the ossicles and their numerous ligamentous connections. These are covered over by folds of mucous membrane which further subdivide the cavity into compartments and which hang down and help to shut off this cavity from the atrium. The posterior part of the attic is directly continuous through the aditus into the mastoid antrum. The external wall is not a thin

The object of after-treatment is to facilitate the discharge from the tympanic cavity through the perforation and to ensure that it is removed from the external auditory meatus and does not lie in a lake against the drum membrane. Efficient after-treatment can therefore influence the prognosis very materially. Many methods of after-treatment are adopted—an effective one is to place a gauze wick right down to the hole in the drum, changing it at frequent intervals, with gentle syringing and the

With rupture of the drum the atrium empties its contents into the external auditory meatus. As free drainage is established resolution of inflammation should occur and the prognosis should be favourable, unless adverse factors are at work, such as a very virulent infecting organism or some lack of resistance on the part of the patient. Old people seem to have a peculiarly low resistance to aural infections.

After-treatment

membrane, as in the atrium, but is formed by the thick bony squama.

When the middle ear becomes infected, the products of suppuration accumulate in the atrium, the Eustachian tube being closed by the congestion of its mucosa and the attic cavity mainly shut off by swelling of the mucous membranous folds of Trösch. As the pressure increases, the wall which offers the least resistance—namely, the external wall which is formed by the tympanic membrane—begins to show signs of the trouble behind it, and the subjective symptoms become correspondingly increased. These symptoms consist chiefly of earache and fever, whilst noises in the head are often complained of and deafness becomes noticeable. The pain may be sudden and sharp and often reaches a point at which it is almost unbearable, making sleep impossible. The temperature is raised and, in children, is often 102° F. and more. The general condition deteriorates rapidly owing to the fever, pain, and sleeplessness. The eardrum shows signs of inflammation and is usually dark red in appearance. The usual landmarks are lost in the general swelling, which is most marked posteriorly and appears to cover the handle of the malleus. A definite bulge of the membrane is seen, most often in the postero-superior quadrant. The light reflex is lost. It should be noted that in very young infants this loss of light reflex may be the only sign in mild cases, and also that bulging of a normal membrane may occur when an infant cries, so that too much reliance should not be placed on this appearance in the very young. In the average case the accumulation of the products of inflammation behind the drum-head causes it to rupture, and this may occur within 24 hours after the appearance of the initial earache, or may be delayed for some days. If the drum is seen before it has ruptured and is bulging it should be incised. It is important that the incision should be carried upwards through the posterior fold and out towards the meatal wall. This will ensure better drainage from the upper compartment and help to prevent the further extension of inflammation. When the drum bursts or is incised there is usually an immediate cessation of pain and a fall in temperature. If the pain stops quickly it is a favourable sign and probably indicates that the suppuration is confined to the atrium as pain due to attic suppuration is much less likely to be relieved at once.

mopping or sucking out of discharge; but I prefer the use of dry insulations of powder, such as 1 per cent. iodine in borie powder, or Dimol, blown into the meatus each day after a thorough cleansing. The mass of dry powder against the drum seems to attract the discharge through the perforation very efficiently and it is quite extraordinary how much discharge the powder can absorb. The powder can be changed once or twice daily. As the discharge diminishes, the congestion of the Eustachian tube subsides and this canal provides a supplementary drain for the escape of fluid from the middle ear. The prognosis with regard to ultimate recovery is good and the drum heals without an apparent scar. The outlook as regards the hearing is difficult to foretell, but is usually good, except in some of those cases in which healing of the drum is, for some reason, unduly delayed.

COMPLICATIONS

If the discharge persists for more than three weeks one may assume that the inflammation is no longer limited but has spread to the attic and, in all probability, to the mastoid antrum as well. It may be that the infection of the attic was a primary one, as in some cases the infection seems to pass through the attic and infect the attic or even the mastoid antrum from the beginning. Be that as it may, the prognosis is now altered for the worse. We have seen that the lining mucosa of the attic hangs in folds across the cavity and this vascular connective tissue forms a suitable medium for the growth of organisms. Moreover, the opening of the attic is comparatively large and any pus which is formed may take the line of least resistance and pass backwards into the mastoid antrum. This involvement of the mastoid occurs in about 25 per cent. of all cases of acute middle-ear suppuration and as this is dangerous, not only on account of the likelihood of chronic suppuration after the acute stage is passed, with damage to the hearing, it is most important that it should be recognised at the first possible moment. It will be remembered that, developmentally, the mastoid antrum is merely a backward extension from the upper part of the tympanic cavity and is present before any mastoid process or cells appear. It is not unusual for some tenderness over the antrum to be present in moderately severe cases of middle-ear suppuration and this usually disappears if the drainage from the middle ear is freely provided for, but if it persists the implication is that the mastoid cells themselves have become infected, the prognosis is not so good, and the mastoid will require opening. Again, reappearance of the discharge after it has stopped or nearly stopped, or the persistence of a very profuse discharge with pulsation, indicates the likelihood of mastoid involvement, as does the continuance or recurrence of pain. The most characteristic sign is a sagging of the postero-superior wall in the deepest part of the meatus.

It would be beyond the scope of this short article to consider the further signs and symptoms of acute mastoiditis and it will suffice to say that, should the surgeon decide that the mastoid is involved, nothing has to be opened, naturally the time of recovery is lengthened, but the prognosis with regard to ultimate repair of the middle-ear suppuration and the restoration of function should not be adversely affected.

CHRONIC SUPPURATION

It is a common experience that a certain number of cases of acute middle-ear suppuration become chronic, urgent requirement.

WEST SURFOLK GENERAL HOSPITAL.—This institution at Bury St. Edmunds is embarking on an extension which will cost at least £25,000. At present there is only one ward for women and some of them have to be accommodated in the children's ward and in a small auxiliary ward. It is not always possible to separate the surgical and medical cases. The provision of a new children's ward is necessary and the present one can then be converted into a second ward for women. A private ward for paying patients is another urgent requirement.

WALTER HOWARTH, F.R.C.S.,
Surgeon to the Ear and Throat Department,
St. Thomas's Hospital.

It will be well to consider to what extent purely conservative measures are likely to be successful in the ordinary case of chronic middle-ear suppuration, and in what percentage of cases the prognosis is a good one. If after removal of adenoids and the adoption of some general cleansing measures for the ear suppuration still continues, a careful course of conservative treatment at the hands of an otologist should result in about 50 per cent. of ears becoming dry. There are many different methods of treatment but the one which gives the most satisfactory results is a modification of the dry method that is advocated for acute cases. In the chronic case it is advisable to clean the ear thoroughly, not only by the external auditory meatus, but the middle ear also by irrigating it through an intratympanic cannula; the ear is then inflated by Valsalva's method to clear the middle ear of fluid, the meatus is again dried, and iodised borie powder is then blown in. In some cases polypi or small granulations may first have to be removed, particularly if the perforation is an attic one, and in these cases the prognosis is not so good, though many heal up quite satisfactorily. Some surgeons advocate the use of zinc ionisation, but I have not been able to satisfy myself that it yields superior results to the above method, and the cases in which it seems most successful—namely, those with large central perforations—are the very ones which respond most quickly to the more simple methods. If healing does not occur in two to three months it is probable that the suppuration is being kept up by some necrosis of the structures in the attic or in the mastoid, and a successful result is not likely to be obtained without a mastoid operation. It may be that a certain proportion of cases are doomed to this from the beginning and many of the most resistant ones may have a definite anatomical basis, as Arthur Cheate suggested many years ago. He found from examination of a large series of temporal bones that in 20 per cent. of all people the mastoid process remains of the acellular type, and that when the middle-ear tract is infected under these conditions and complete resolution does not take place or other complications occur, the disease passes into a chronic stage which may continue indefinitely and be associated with more or less destruction of the tympanic structures and the formation of polypoid granulations and cholesteatoma. In these cases a mastoid operation is necessary if the cure of the middle-ear suppuration is to be effected.

SPECIAL ARTICLES

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

SECTION OF DERMATOLOGY

Dr. S. WATSON SMITH (Bournemouth) presided at a meeting of this section when Dr. HERMAN LAWRENCE read a paper on the incidence of

Skin Diseases in Australia

He compared the order of the commoner skin diseases in England, America, and Australia, and explained the reasons for these variations. Eczema, dermatitis, and seborrhoea occupied first place in all three countries. In England the second place was taken by ringworm, pediculosis, and scabies, whereas these hardly came into the picture at all in Australia owing to the difference in social conditions. The climate of Australia favoured an out-of-door life; the poorer classes lived in separate dwellings and had greater conveniences for personal cleanliness. In Australia the second place was filled by a group consisting of rodent ulcers, keratoses, and epithelioma. This was due to two factors: (1) the increased amount of sunlight, and (2) the relatively low humidity. Adelaide had double the amount of sunlight and nearly half the humidity of London. In central Australia the average amount of sunlight was over 3000 hours per year, and the humidity under 30 per cent. The temperature was also much higher, rising to over 115° F. in the shade. The amount of ultra-violet light reaching the skin was therefore very great. Many of the patients had marked keratoses of the face, hands, ears, and fore-arms, without any signs of malignancy developing. After a history of the patient picking at the lesion, or perhaps of the application of CO₂ snow, one of the lesions would rapidly enlarge, and a frankly malignant epithelioma would develop. Italians and aborigines were almost free from these troubles. The bathless and sun-bathing cult, whilst lessening the likelihood of parasitic disease and skin tuberculosis, was a real menace in Australia as the cause of cancerous or precancerous lesions. Dr. Lawrence then described some rarer skin diseases of interest:—

Favus.—In 1917 a plague of millions of mice appeared in Queensland and travelled 1500 miles into South Australia. Some of the mice developed skin diseases which they passed on to human contacts. Many of the lesions were due to a parasite of the ringworm order, but the most troublesome ones from the point of view of treatment were due to an abortion—the *Achorion quinckianum*. X-ray therapy was of great value, especially in lessening the pain and shortening the time required for cure. Since 1917 there had been several minor troubles of this nature, and it was recognised that cases of favus, both in human beings and in mice, were more or less continuously present.

Dermatissus avium et galline.—During the past 30 years Dr. Lawrence had many times found the dermatissus to be a cause of pruritus in patients who had nothing to do with poultry yards, and in several cases he had actually traced the parasite to abandoned birds' nests near windows. He suggested that *Dermatissus avium* was often to be found in nests, and was a more common cause of pruritus than was generally known; text-books made little or no mention of it. It was often difficult to trace the cause of the pruritus to these parasites, as they were nocturnal in their habits, generally hiding in the daytime. The nests of starlings, pigeons, and sparrows were most likely to harbour them.

"Collision value."—When gamma rays from one direction collided with beta rays from the opposite direction, their combined action was termed by Dr. Lawrence "collision value." He made use of this action in the treatment of keratoses and rodent ulcers. The radium was held in metal holders and earthed. A high-frequency current was applied, with the patient standing on an insulated mat. In this way there was a veritable battlefield of rays and particles up to about 1 cm. distant. The treatment was rapid and effective, but care must be exercised lest the absorbed beta particles produce necrosis of the tissues.

Dr. W. UPTON (Adelaide) in analysing 3000 cases, had obtained figures similar to those of Dr. Lawrence, but in his series scabies and ringworm were more common. One case in eight was in the keratosis—rodent ulcer—epithelioma group. Many of these were elderly women leading an outdoor life and using no cosmetics. He had seen 5 cases (in 25) of lupus erythematosus developing after severe sunburn. Grim itch was a common disease in South Australia. Lip cancer occurred in non-smokers after prolonged sunburn and cracking of the lips.

Dr. F. H. MACKY (Adelaide) gave an analysis of 3000 patients treated at a cancer clinic. In these there were 1774 skin lesions, hyperkeratoses accounted for 456, squamous-celled carcinoma 431, and rodent ulcers 887—many patients had multiple lesions. In addition, there were 188 cases of lip carcinoma. Nearly all were proved microscopically. Multiple keratoses were best treated by X-rays. Ringworm of the feet and dhotie itch were common in South Australia, and cases of scabies seemed to be increasing.

Dr. J. M. O'DONNELL (Perth) also found hyperkeratosis a common complaint, particularly on the gold-fields. Psoriasis, ringworm of the scalp, and dhotie itch were common, and scabies was increasing. An epidemic of grain itch had occurred amongst wheat labourers.

Dr. J. WITTON FLINX (Sydney) had found epidermophyton often enough to justify its inclusion in the 15 most common skin diseases.

Dr. J. H. KELLER (Melbourne) had also found that sunburn predisposed to lupus erythematosus. Syphilitic diseases of the skin were now quite rare. The President agreed that the low humidity and factors predisposing to skin cancer. Favus was unknown in England but common in Scotland. Dhotie itch was frequently found in boys' schools.

Dr. J. IVAN CONNOR (Melbourne) read a paper on the treatment of

Staphylococcal Infections of the Skin

Irritation was dramatically relieved following the treatment, and the vesicles rapidly resolved. In the later stages, when eczema had supervened, ichthyol and salicylic applications were employed. An infective focus must be eliminated to prevent recurrence. When the fungus element had died out, and sensitisation to external irritants remained, removal of toxic foci and autogenous vaccines might help. Intravenous calcium therapy and high colon lavage were also used with success in these types.

DR. J. WITTON PLYNN (Sydney) said that epidermophyton was very common in Sydney, many cases being symptomless and ignored by the patient. Dressing sheds and gaols were places where the infection was easily spread. To check the disease the spread from one person to another must be prevented by keeping the feet covered and dry, and by dusting with a mild acid antiseptic powder. The floors of dressing sheds must also be kept as dry as possible. Reinfection could be prevented by treating the chronically inflamed toe-nails and correcting orthopaedic faults. Whitfield's ointment was, in his experience, of little value.

DR. S. W. SHIELDS (Melbourne) thought the disease more prevalent now owing to the increased amount of sport and to the popularity of trips to the tropics; moreover diagnosis was more accurate. The borrowing of towels in schools and camps was one of the common methods of infection. He had found Whitfield's ointment fairly satisfactory.

DR. BUTLER (N.S.W.) said that at one time 90 per cent. of the military cadets at Dunrobin had "Dunrobin rot" between the toes. The use of lotio potassium permanganate before and after baths and borie acid between the toes produced good results, but where the nails were involved treatment was less effective.

The President thought that the variable results obtained with Whitfield's ointment might be explained by variation in its composition, and by the fact that some patients did not rub it in vigorously enough. Spirituous solutions of aniline dyes were well worth trying.

SECTION OF PHARMACOLOGY, THERAPEUTICS AND ANÆSTHESIA

Prof. SYDNEY SMITH presided at a meeting of this section when Sir WILLIAM WILCOX opened a discussion on the

Use and Abuse of Hypnotic Drugs

He said that the advances in the study of hypnotics since 1913 included the discovery of many new derivatives of the barbituric acid series and the introduction of drugs other than alkaloids for basal anaesthesia. Insomnia was due either to psychological or organic causes and it was essential before commencing treatment to discover the cause. Hypnotics should be used only when absolutely necessary and when treatment by the usual general measures was unsuccessful. Patients taking hypnotics were likely to lose self-reliance and form the habit. Many operative cases did not require morphia or heroin, and as a routine they should not be administered post-operatively. Deaths from suppression of urine following their too free use were not uncommon. A dose of only 1/8 to 1/12 of a grain should be given, and repeated if necessary. The perfect hypnotic had

natural antitoxin of the patient at a high titre. by injections of toxoid to stimulate and maintain the acute infection, could be followed during convalescence the remainder much improved. Antitoxin, given in an infections, mainly furunculosis, is cured and the rest so improved that they ceased to attend treated with toxoid, 12 were regarded as cured, and series of 23 cases of syccosis barbe and syccosis nuchæ (12 c.cm.). The toxoid lost 40 per cent. of its antigenic power in six months in the ice-chest. In a many more. Forty had been given in one case cured furunculosis, but syccosis barbe often required after an intermission. Eight injections usually when beginning treatment, or on resuming injections It was wise therefore to start with very small doses occurred after the early injections of the series. percentages of cases, local, focal, and general reactions according to the patient's reaction and condition. 0.05 c.cm. was used, gradually increased weekly the treatment by toxoid injection a small dose of improvement in the clinical condition in man. In This produced an immunity in animals and an the titre of circulating antitoxin as much as 20 times. days, a toxoid was produced which could increase staphylococcal exotoxin with formalin for several

DR. JOHN C. BELSARRO (Sydney) read a paper on

Mycological Infections

Vesicular eruptions on the feet and hands, he said, were very common in Sydney. There were several clinical types: (1) superficial vesicular and (2) deeper vesicular, both these being on the fingers, toes, palms of hands, and soles of feet; (3) localised type; (4) scaling or eczematoid type; (5) intertriginous type, remaining localised to the interdigital spaces; and (6) hyperkeratoid type. Many of the vesicular manifestations represented an allergic reaction of the tissues to toxins liberated from primary foci of infection. The numerous reticulated factors—seasons, exposure, food, orthopaedic abnormalities, and so on—might all produce their effect by altering the reaction of the sweat. Normal sweat had an acid protecting cloak, but the sweat of the hands and feet was neutral or alkaline, owing to the absence of sebaceous glands and lack of evaporation. Alkaline sweat appeared to favour mycæal growth. Working on this hypothesis, lemon juice was tried; citric acid, apart from its effect on pH, also had a buffer action. The juice was used 4-5 times a day, in conjunction with liquor plumbi sub-acetate 1 per cent. hydragry ammon. dil. in lanoline, for.

yet to be discovered. Sir William classified hypnotics into the following groups:—

Low toxicity group—e.g., bromides, alcohol, Phenazone, Pyramidon, phenacetin, aspirin.

Chloral and its associates—Chloral was effective, safe, and rapid in action. Other drugs useful in this group were chloralamide, butyl chloral, chloralose, Chlorotone, paraldehyde (freely diluted) and Avertin.

Avertin was used extensively as a basal anesthetic. It sometimes produced toxic liver effects.

Urea group—Aldabin was very safe and very useful. It was best administered in a dose of 10 grains combined with a similar dose of aspirin.

Suphone group—Suphonal and trional were examples; they were slow in action, uncertain, and toxic. Skin rashes and toxic symptoms were not uncommon following their use.

Barbituric acid group—This group contained a great many preparations, whose toxicity depended on the molecular weight of the molecule combined with the barbituric acid; the heavier the molecular weight the greater the toxicity. They were quickly absorbed, certain, and very good in selected cases. Idiosyncrasy was not uncommon. Thyrotoxicosis, asthma, and its related diseases, affections of the kidneys, liver, and adrenals rendered patients highly susceptible to barbiturates, and these should therefore be used only after such conditions had been excluded by thorough examination. Sir William cited cases of fatal suppression of urine and heart failure following repeated taking of normal doses could produce curious manifestations amongst which were diplopia, squint, visual hallucinations, ataxia, and degenerative changes of the central nervous system. These were frequently attributed to cerebral tumour or other intracranial diseases. Accumulation of effects occurred, but chemically no accumulation in the tissues could be detected even after long periods of administration. Tolerance was not established to barbiturates, but the habit of taking them could be formed. They caused amnesia, and in this way could be responsible for suicide; an actress had walked out of an open window following only a small dose of a barbiturate. In big doses these drugs not infrequently caused fatal pneumonia. Overdosage should be treated by bowel and gastric lavage, caffeine as a diuretic and drainage of cerebro-spinal fluid by lumbar or cisternal puncture. To cerebro-spinal fluid drainage many good results in treatment were attributed.

Alkaloidal hypnotics—Morphia and heroin should not be used in the presence of hepatic or renal deficiency. In selected cases free but not prolonged use should be made of them, in adequate dosage. Apomorphine hypodermically was a good hypnotic in delirium tremens. It produced nausea followed by sleep.

Basal anesthetics—Amytal, Nembutal (grs. 5), Evipan, and others were useful but dangerous if idiosyncrasy existed. Sir William had seen a case of pneumonia after the administration of 3 grains of Nembutal. In conclusion, he said that in prescribing of the less toxic drugs should be selected. If a barbiturate were to be administered, the patient should be examined for the abnormalities likely to cause idiosyncrasy.

Prof. R. D. RUDOLF (Toronto) congratulated Sir William on his fair and moderate statement. He considered insomnia to be due either to increased irritability or increased irritation of the central

Dr. R. DAVIES (Melbourne) asked whether barbiturates should be used in cases of pneumonia.

Dr. N. W. MARKWELL (Brisbane) said that chloral and bromide were the best hypnotics in pneumonia, especially for the post-febrile insomnia. For post-critical delirium chloroform anesthesia and gastric lavage were used, but he gave 1 drachm of bromide hourly until sleep ensued. One patient had been given 1 ounce in 12 hours. He asked Sir William what was the best hypnotic in this condition. He pointed out that in coronary thrombosis large doses of morphia could be safely given. In cases of threatened nervous breakdown he used barbiturates in adequate dosage and stopped their use gradually.

Dr. D. G. KEXTON (Melbourne) asked if a second dose of paraldehyde was less effective than the first, and whether barbiturates ever caused excitement. He gave his own experience of amnesia for 24 hours following 12 grains of sodium amytal administered in divided doses; in his own case morphia relieved pain but did not induce sleep. He confirmed the good effects of chloral and bromide.

Dr. W. SIMMONS (Sydney) asked what hypnotic Sir William recommended for the insomnia of pregnancy.

Dr. Z. MEXELL (London) said that he could not persuade Sir William to take a barbiturate for sea-sickness on the voyage out from England. Hedonal (not a barbiturate) was used frequently in Russia, where it was the cause of much pneumonia. He stressed the amnesia and the dangerous toxic symptoms produced by barbiturates in hypersensitive patients. Synergism played a large part and was well exemplified by the marked effect of small doses of morphia with barbiturates. Cerebro-spinal fluid drainage was of great value in treating toxic symptoms due to the barbiturates. Morphia was preferable to heroin because the former was less depressing to the respiratory centre. Depression to respiration by heroin was very marked when it was used in conjunction with evipan. Intravenous morphia was useful but great care was necessary.

Dr. B. L. STANTON (Melbourne) said there was an accumulation of effects following small doses of the barbiturates. This was evidenced by the marked effects produced by repeated small doses in the treatment of high blood pressure. The nervous irritability of children should be treated with small doses of barbiturates. He had treated a case of cerebral poisoning but sent the patient into a deeper coma. This was evidence of synergism. The combination of codeine and aspirin was a good hypnotic and analgesic.

Dr. IVAN MAXWELL (Melbourne) said that ephedrine given in cases of asthma had often caused wakefulness, so he prescribed luminal or amytal as a sedative. Idiosyncrasy to small doses of aspirin was common in asthmatics, but no sensitivity to it was demonstrable in skin tests. He inquired whether luminal or bromide was preferable in the treatment of epilepsy.

Sir WILLIAM WILCOX said that he did not recommend the use of barbiturates in pneumonia because no other drugs were so likely to cause bronchopneumonia, and in addition they were not sufficiently powerful. For post-critical delirium he preferred hot packs and tepid sponges to drugs, which should only be used after physical measures had failed. He thought large doses of bromide were useful but would hesitate to use as much as 1 drachm hourly. However, the proof of the pudding was in the eating. He recommended that when barbiturates were required, well-known ones like veronal and Medonal should be prescribed. He agreed that a second dose of paraldehyde was not as effective as the first. Barbiturates often caused excitement. Morphia often relieved pain without inducing sleep, and sometimes caused excitement. The effects of the barbiturates were cumulative; a patient who had received 1 gram of luminal daily for one year had developed toxic jaundice. Veronal in usual doses took 2-3 days to be excreted. The barbiturates and morphia should not be used for the insomnia of pregnancy, since the effect of the hypnotic on the child had to be considered. It was best to adopt simple physical measures, and if hypnotics were required aspirin or alcohol should be administered.

Prof. W. A. OSBORNE (Melbourne) read a paper on the Vasoconstrictor Principle in the Skin of the Frog (*Hyla Aurea*)

He said that when experimenting on a frog he became very painful but not blood-shot. This chance observation led him to further experiments. He made an extract of the frog's skin which on injection consisted of the peripheral arterioles, completely closing them. The heart stopped beating as a result of coronary spasm, and the blood pressure remained high. The experiment had been repeated and the result confirmed. He knew of no other drug which produced complete obliterative spasm of the arterioles. The effect of the extract was only slightly reduced by boiling. He suggested that this curious principle in the skin of the frog might some day find a clinical application.

Urinary Antiseptics

Mr. JOHN TAIT (Melbourne) opened a discussion on

He said that antiseptic drug treatment of infections of the pelvis of the kidney must be ineffective because the pelvis emptied so frequently. In determining what could be expected from drug treatment the basal pathology of the various urinary tract infections had to be considered. A great many infections were blood-borne. The gall-bladder had been the origin of the infection in one of his patients who had been cured of a chronic pyelitis by cholecystectomy. The majority of the infecting organisms came from the bowel. If they were not destroyed by the normal immunity mechanisms they could cause urinary tract infections. Mental exhaustion was the main cause of impairment of the normal mechanism. Chronic pyelitis was a disease of professional people. A small number of cases of chronic pyelitis gave a history of bowel infections. There was great difficulty in curing these infections by drugs. Hexamine (urotropine) was the most useful. He quoted a case of chronic pyelitis who had been kept comfortable with hexamine for years. Hexamine should be given between meals when the gastric acidity was at its lowest. Hexyl resorcinol (Caprokol) was not more effective than hexamine.

Sir WILLIAM WILCOX agreed with the remarks of Mr. Tait and Mr. Mortensen. Changes of antiseptics were beneficial. One drachm of potassium citrate 3-4 times daily for 3-4 days at intervals of 3-4 days was useful. Metromene (methylene-bis and hexamine) was used a lot in England apparently with good results. An autogenous vaccine was of value in treatment and also vitamins A and D in building up immunity. Hexamine salicylate (Cytotrophin) intravenously was effective in acute toxic conditions arising from the urinary tract.

Mr. MORTENSEN, replying to Dr. Maxwell, said he preferred catheterising a patient 2-3 times daily with Sir William concerning the beneficial effects of cytotrophin.

Dr. MAXWELL said that hexamine for its antiseptic action required a concentration of pH 5 and needed to be in contact with *B. coli* for six hours to destroy it. The pH was difficult to obtain clinically and it was almost impossible in cases of acute cystitis to keep the urine in the bladder for several hours. Similarly in pyelitis, contact with the antiseptic was not sufficiently long. Hexamine in cases of retained catheter did not prevent infection.

Sir WILLIAM WILCOX agreed with the remarks of Dr. Tait and Mr. Mortensen. Changes of antiseptics were beneficial. One drachm of potassium citrate 3-4 times daily for 3-4 days at intervals of 3-4 days was useful. Metromene (methylene-bis and hexamine) was used a lot in England apparently with good results. An autogenous vaccine was of value in treatment and also vitamins A and D in building up immunity. Hexamine salicylate (Cytotrophin) intravenously was effective in acute toxic conditions arising from the urinary tract.

Mr. H. MORTENSEN (Melbourne) said the antiseptic properties of drugs depended on the form in which they were excreted in the urine. Some antiseptic drugs caused a beneficial effect by their diuretic action. Secondary infection was frequently the first sign of some lesion, such as calculus, of the urinary tract. The three types of urinary antiseptics were: those derived from plants, for example, buchu which probably acted by its diuretic effect; those having a direct antiseptic action; and those which altered the reaction of the urine. Hexamine and acriflavine were probably the best. Hexamine was irritating to the alimentary canal and might produce acidosis. N.A.B. was effective against the urine, large doses of potassium bicarb. or potassium citrate should be used. Beta-hydroxybutyric acid was the factor which inhibited *B. coli* in patients taking a ketogenic diet. A reaction of pH 5.2 to 4.6 was required in vitro. Twelve grammes of mandelic acid and 8 grammes of ammonium chloride daily were effective.

Mr. H. MORTENSEN (Melbourne) said the antiseptic properties of drugs depended on the form in which they were excreted in the urine. Some antiseptic drugs caused a beneficial effect by their diuretic action. Secondary infection was frequently the first sign of some lesion, such as calculus, of the urinary tract. The three types of urinary antiseptics were: those derived from plants, for example, buchu which probably acted by its diuretic effect; those having a direct antiseptic action; and those which altered the reaction of the urine. Hexamine and acriflavine were probably the best. Hexamine was irritating to the alimentary canal and might produce acidosis. N.A.B. was effective against the urine, large doses of potassium bicarb. or potassium citrate should be used. Beta-hydroxybutyric acid was the factor which inhibited *B. coli* in patients taking a ketogenic diet. A reaction of pH 5.2 to 4.6 was required in vitro. Twelve grammes of mandelic acid and 8 grammes of ammonium chloride daily were effective.

Dr. MAXWELL said that hexamine for its antiseptic action required a concentration of pH 5 and needed to be in contact with *B. coli* for six hours to destroy it. The pH was difficult to obtain clinically and it was almost impossible in cases of acute cystitis to keep the urine in the bladder for several hours. Similarly in pyelitis, contact with the antiseptic was not sufficiently long. Hexamine in cases of retained catheter did not prevent infection.

Sir WILLIAM WILCOX agreed with the remarks of Dr. Tait and Mr. Mortensen. Changes of antiseptics were beneficial. One drachm of potassium citrate 3-4 times daily for 3-4 days at intervals of 3-4 days was useful. Metromene (methylene-bis and hexamine) was used a lot in England apparently with good results. An autogenous vaccine was of value in treatment and also vitamins A and D in building up immunity. Hexamine salicylate (Cytotrophin) intravenously was effective in acute toxic conditions arising from the urinary tract.

Mr. MORTENSEN, replying to Dr. Maxwell, said he preferred catheterising a patient 2-3 times daily with Sir William concerning the beneficial effects of cytotrophin.

Of the antiseptic dyes Pyridium and Neotrophin were good and very penetrating. Flavine and mercurochrome applied locally were often effective in concentrations of 1 in 400, but much higher ones could be used if the state of the kidney pelvis permitted. Intravenously these two drugs were not efficacious. A combination of methylene-bis and sandalwood oil was a good sedative antiseptic. It was desirable in addition to drug treatment to control the source of the infection, to put up the immunity response, and to promote a free flow of urine.

Mr. H. MORTENSEN (Melbourne) said the antiseptic properties of drugs depended on the form in which they were excreted in the urine. Some antiseptic drugs caused a beneficial effect by their diuretic action. Secondary infection was frequently the first sign of some lesion, such as calculus, of the urinary tract. The three types of urinary antiseptics were: those derived from plants, for example, buchu which probably acted by its diuretic effect; those having a direct antiseptic action; and those which altered the reaction of the urine. Hexamine and acriflavine were probably the best. Hexamine was irritating to the alimentary canal and might produce acidosis. N.A.B. was effective against the urine, large doses of potassium bicarb. or potassium citrate should be used. Beta-hydroxybutyric acid was the factor which inhibited *B. coli* in patients taking a ketogenic diet. A reaction of pH 5.2 to 4.6 was required in vitro. Twelve grammes of mandelic acid and 8 grammes of ammonium chloride daily were effective.

MALARIA IN CEYLON

MUCH that has been written about the epidemic of malaria in Ceylon is inaccurate or misleading; but with the publication of reports¹ by Colonel C. A. Gill and Dr. Rupert Briere-Light we now have an official account of it. Dr. Briere-Light is director of medical and sanitary services in the island; Colonel Gill, formerly chief malaria medical officer and director of public health, Rangoon, was appointed as expert adviser on malaria by the Ceylon Government during the epidemic. The former states that his report is concerned chiefly with facts and figures, while the latter reviews the facts and deduces the policy that should be followed by the Government of Ceylon in the future. From these reports we learn that the epidemic is the greatest pestilence in the recorded history of the island. In seven months it destroyed 80,000 lives, and indirectly it caused incalculable misery and distress; for it interrupted trade and business, paralysed village life, and led to an almost complete cessation of agricultural operations for a long period with consequent dire privation and starvation.

Although there had been previous epidemics on a large scale, and although two-thirds of the island—the north, east, and south-east parts of Ceylon—once densely populated, are now so malarial that they contain only about 1 per cent. of the population, this outbreak came as a bolt from the blue. In the last week of October and first week of November, it appeared as an "explosive outbreak" in an area of about 5800 square miles. The peak of the epidemic was judged by sickness in the middle of December, 1934, and as judged by mortality in the middle of January, 1935; from then it slowly declined except for a small rise in May and June. At the height of the epidemic there were 60,000 attendances a day at the government institutions in the affected area, and by the end of April 1½ million cases. Curiously enough this epidemic area was situated between the intensely malarial area in the north, and an area in the south-west, where there is little malaria normally, and which even during this epidemic was little affected.

Part of Colonel Gill's report is occupied by a discussion of the cause of the epidemic. He considers an epidemic "was due, if not overdue." He acknowledges very properly the valuable work during the past 12 years by Mr. H. F. Carter, medical entomologist, who had incriminated *Anopheles culicifacies* as the chief, if not the only important carrier of malaria in Ceylon, and who provided him with full information on the bionomics of the 18 species of *Anopheles* in the island. *Culicifacies* breeds in rock and sandy pools in the beds of rivers, but it is also found in many other situations, like wells, borrow pits, quarries, drains, pools, and sheets of water formed during the rains. In most years the rains flush the rivers and sweep away the larvae, but during droughts the larvae are undisturbed and hatch out in enormous numbers; hence the association of malaria with rivers in Ceylon which has long been recognised. Colonel Gill sounds a warning that mosquito control in the river-beds alone is not likely to be successful. The permanent malaria in the north, east, and south-east parts of Ceylon receive rain from the north-east monsoon in October, November, and December; in these there is a single malaria wave with a broad

SYMPTOMS AND TREATMENT

On the clinical side the predominating parasite is reported as *Plasmodium vivax*; but there is some doubt whether the microscopic work in many hospitals was accurate. A special study of 647 cases showed that besides the common type of fever, there were cerebral cases, algid cases, diarrhoea and dysenteric types, oedematous types, and malaria complicating pregnancy often with disastrous results. In the treatment of malaria during pregnancy Dr. G. A. W. Wickramasuriya considered that "far from being an oxytocic, quinine administered in effective therapeutic doses, by rapidly controlling the malarial infection and the high temperature, prevents premature interruptions of pregnancy and intra-uterine fetal death," and his views have been generally confirmed by other medical officers. The association of ankylostomiasis, or malnutrition, with malaria was regarded as the cause of the partial or generalised oedema which occurred in a large number of cases in the later stages of the epidemic, chiefly among children.

Colonel Gill discusses the distribution of the malaria and the epidemiology; but despite certain correlations between rainfall and malaria, and full entomological data, "the entomological theory does not appear competent to explain the whole phenomenon presented by the epidemic and the intriguing paradox therefore remains that malaria epidemics in tropical Ceylon are determined by drought, whilst in sub-tropical India they follow excessive rainfall." An attempt is made to explain the paradox, by suggesting a periodicity of the parasite, "possibly the quality variation referred to as 'the unknown influence' the 'X factor' of Pettengkofers, the epidemic potential, and 'the general determining cause' of modern epidemiologists. Whatever may be its nature, the predominant attribute attaching to periodicity as the variable amplitude of its range." If other conditions are not favourable even this universal "influence" cannot produce an epidemic. And so in spite of a highly congested population containing a high percentage of susceptible children, in spite of the presence of drought, in spite of special hardships from economic conditions, and in spite of the presence of river-beds, the "influence" had little effect in the south-west area of the island, where the carrier insect, although present was not widely prevalent. Nor had the "influence" much effect on the permanently higher malarial area.

Altebrin and Atebrin mussonate were used in

hospitals, but were not considered suitable for use at effects. Comparing atabrin and quinine an appendix to Dr. Briereville's report states:—

"Deaths.—Among 681 patients treated with atabrin 17 or 2.5 per cent. died and among 424 treated with quinine 6 or 1.4 per cent. died. Four of the 17 deaths following atabrin miasmata were attributed to the toxic effect of the drug. If these four cases are excluded, the natural death-rate among the atabrin treated cases would have been 1.9 per cent., which is not significantly greater than the death-rate for the quinine treated series."

Discussing the toxic effects and the sudden deaths after atabrin injections, the appendix states that—"among adults, pregnant women have been found particularly liable to collapse after injections. Convulsions due to malaria were of frequent occurrence among children in the early stages of the epidemic. Convulsions occurring a few minutes or hours after an atabrin injection and attributed by the medical officer concerned to the atabrin injection have occurred in both children and adults. They were always fatal."

PROPOSALS FOR THE FUTURE

In Part II. of his report, on the Control of Malaria in Ceylon, Colonel Gill discusses the scientific problem under the headings, the mosquito factor, the parasite factor, and the human factor, and summarises this by saying endemic malaria in Ceylon presents no novel or remarkable features. Although these epidemics have hitherto been regarded as uncontrollable, there is now reason to believe that their emergence can be prevented if measures are taken that will reduce the spleen-rate and the anopheline-rate (*A. culicifacies*) to the level of these factors in the south-west healthy area. This will take time, but can be accomplished if medical science provides the technical knowledge, Government the machinery, and public opinion the motive power. Government having decided that the population is sufficiently advanced politically to control its own internal administration, the success of the scheme will depend on the actual co-operation of the people. Colonel Gill reminds them that so far only a few antimalarial schemes had been begun in Ceylon, and had achieved only a certain measure of success—not from any fault in the schemes, but from lack of popular interest resulting in a lack of funds to complete or maintain them. The recent epidemic, however, has produced a profound change in public opinion.

GENERAL DISEASES

During the first few days Venereal disease was considered from the international standpoint. It was accepted as a fact that syphilis and gonorrhoea could be made extinct throughout the world within a single year if all who suffer from them would have themselves fully treated. Starting from this principle the Congress proposed the application of legal penalties and the State control of treatment, together with the regulation of prostitution. From this it passed on to discuss some of the social questions arising in the practice of dermatology and venereology, including out-patient dispensaries, sick clubs, beauty specialists, barbers, masseurs, and quacks. Prof. Kertl (Vienna), in an address lasting several hours, pointed out that while specialists in dermatology and venereal diseases keep strictly to their own territory, practitioners in adjacent fields press ever harder on their confines; indeed, it is often suggested that the treatment of syphilis is rather than the business of the internist and the neurologist. The latter must gain exact knowledge of the borderline of his subject—even if it means adding a couple of years to his training—and that when he has such knowledge even neurosyphilitic affections should come within his province.

ALFREDUR (Stockholm) early created a sensation by proposing that the present division of syphilis into three stages should be abandoned; by means of many histological preparations he demonstrated that this infection, at all stages and in all places, will always produce what is essentially the same lesion. This view was accepted by many other pathologists present but on the whole was considered unproven. GRUYERER, who has been studying the nature of the Wassermann reaction, reported that he has obtained positive tests from healthy animals treated with "spirochaete lipoids," whereas previous treatment with non-specific "organ lipoids" did not yield the same results. SCHERRECHENBERG (Paris) made known his successes in the treatment of syphilis

THE CONGRESS OF DERMATOLOGY (FROM OUR NEAREST CORRESPONDENT)

Institute in commemoration of the Jubilee; Colonel Gill recommends that a malaria department be accommodated in a wing of a main institute. He states his proposals will cost money; "good health, including freedom from malaria, is a purchasable commodity, but it is doubtful whether it is worth having as a free gift." Financially stricken as the island has been by the world depression and people of Ceylon have now the anxious task of deciding how the maximum benefit is to be obtained from the minimum expenditure; which of Colonel Gill's recommendations are to be carried out now and which postponed; for Colonel Gill says of this, "balanced scheme" that "many parts indeed can be postponed or omitted without destroying its general structure."

No attempt is made to frame an antimalarial scheme for adoption in each individual area. Colonel Gill recommends provision of hospital facilities and that apothecaries and dispensers in the Government and estate hospitals and dispensaries be replaced by registered medical practitioners provided with more accurate; this is to control the parasite factor in man. Malaria control schemes should be undertaken in urban, rural, and estate areas; by land drainage, irrigation and development schemes, and river training operations. He deprecates colonisation schemes which involve the introduction of non-immune settlers into hyperendemic areas; and he considers antimalarial measures in such areas will not be effective unless accompanied by measures designed to promote rural betterment by increasing the food-supply and relieving economic distress.

The recommendations include establishment of a Sanitary Works Board, with the Minister of Local Government as president, and an equal number of official and unofficial members. It is also advised that an Anti-Mosquito Ordinance be passed. A proposal had been made to erect a Malaria Research

in animals by means of a guinea preparation of his own, but it was felt that further evidence of its efficacy was required. Also in the discussions on syphilis an interesting dispute arose between Arzt and Kertl, both leading clinicians of Vienna, about the importance to be attached to early changes in the cerebro-spinal fluid. Arzt looks on these changes as an indication for treatment with malaria, whereas Kertl upholds the conventional view that they are mostly transitory. FIZARD (Paris) took the view that fever therapy is desirable in syphilis (1) if the blood-serum is obstinately positive, or (2) if there is a positive Wassermann reaction of the cerebro-spinal fluid or other evidence of neurosyphilis. If the blood Wassermann cannot be made negative he prefers subpyrexia in neurosyphilis and G.P.I. he uses malaria, or subpyrexia if it fails. LUDWIG WINKLER (Oradea, Rumania) drew attention to his priority as advocate of subpyrexia therapy in neurosyphilis, and spoke of its value in cardiovascular and arthritic syphilis as well. He also referred to the importance of estimating the erythrocyte sedimentation-rate as a control of cure of syphilitic infection. HILGERMAX (Landsberg) and SPRITZER (Vienna) gave an account of their method of inoculation with a spirochete vaccine, which they believe makes the organisms of syphilis accessible to chemotherapy.

The five largest American clinics reported their experience of cardiovascular syphilis; it appeared that in 6553 cases of syphilis—treated early, late, satisfactorily, unsatisfactorily, or not at all—the percentage of cardiovascular complications was 9.9; while in the smaller group, comprising only those which had not been treated early enough, it was 23 per cent. The Americans are the champions of uninterrupted treatment at all stages of syphilis. Gonorrhoea did not receive as much attention as sometimes. Austrian and German members of the Congress expressed doubt about the value of the serological reaction, which they considered very optimistic to use this reaction as a criterion for treatment. As regards actual remedies no advance worth mentioning seems to have been made during the past few years. The horse serum injections proposed by Szilvassy have proved useless in GUSZAKY'S hands, and all the speakers seemed to agree that vaccines are valueless in the acute stage, while their action on complications is probably not specific. Of new preparations methylene-blue and acridine dyes seem to be the only ones which represent an improvement. Goldberger's abortive cure with Tryparazine was received very dubiously, and some rejected it altogether.

SKIN DISEASE AND THE BODY AS A WHOLE

With the object of increasing the international solidarity of dermatologists a number of committees were appointed to go into such problems as cutaneous tuberculosis, industrial and other environmental affections of the skin, and the classification and nomenclature of skin diseases. This last committee, under the leadership of Howard Fox of New York, is faced with a difficult task of reconciling many different attitudes; it has to bear in mind the different effects of identical causes and the identical effects of different causes, the individuality of the patient, the transitory nature of symptoms, the varying violence of malades, and the accumulation of diverse processes. In the present state of knowledge no system of eternal validity can be laid down, but one can imagine a working classification which would adapt itself to the advance of knowledge.

LEVADITI (Paris), NICOLOAU (Bucharest), and others introduced the important subject of the filtrable viruses, and spoke of the proof that lymphogranuloma inguinale is due to a virus and can be recognised with the Frey antigen. URSACH and WOLFMAN reported that pemphigus vulgaris and dermatitis herpetiformis are likewise due to a virus, while NEUBER (Debrecen) stated that that rhinoscleroma is caused by a capsulated bacillus—findings which will be of great interest provided that they can be corroborated. MAX-SHNEIDER (Essen) brought forward statistics supporting the Russian view that lupus tuberculosus. He denies that phthisical patients are particularly liable to contract lupus; indeed, he finds that their illness tends more towards recovery when they do so. Also speaking on lupus, AITKIN (Edinburgh) said that among 270-280 cases he had found that about half followed tuberculous infection of glands of the neck. It was very important, he said, that practitioners should recognise the great value of ultra-violet irradiation for tuberculous adenitis.

Elsewhere the Congress provided evidence of a reaction against methods of irradiation in dermatology; it was evidently felt that these have been

Much was said about the action of vitamins on the skin, and several speakers assumed that they have a preventive or curative action; a Hague professor, for example, reported good results from the use of vitamin-rich raw foods in conditions such as psoriasis and eczema. The importance of dietetic treatment in skin diseases where the patient suffers also from digestive disorders was fully recognised. Due consideration again was given to the role of focal infections.

LEVADITI (Paris), NICOLOAU (Bucharest), and others introduced the important subject of the filtrable viruses, and spoke of the proof that lymphogranuloma inguinale is due to a virus and can be recognised with the Frey antigen. URSACH and WOLFMAN reported that pemphigus vulgaris and dermatitis herpetiformis are likewise due to a virus, while NEUBER (Debrecen) stated that that rhinoscleroma is caused by a capsulated bacillus—findings which will be of great interest provided that they can be corroborated. It was very important, he said, that practitioners should recognise the great value of ultra-violet irradiation for tuberculous adenitis.

Elsewhere the Congress provided evidence of a reaction against methods of irradiation in dermatology; it was evidently felt that these have been

carried to excess. FRANKS POTTER has not found short and ultra-short wave therapy particularly valuable; physicians from the United States quoted cases which suggest that diathermy is just as efficacious. To sum up, although this Ninth Congress brought no great new discovery it has cleared up many problems of diagnosis and treatment and brought out new principles and objectives. Apart from skin diseases caused by external infections, it seems that the time is not far distant when the use of ointments in dermatology will be almost extinct. What has become chiefly important, for efficient diagnosis and for efficient treatment, is a knowledge not of the changes discovered but of their underlying causes.

LONDON WATER

SOME PRESENT-DAY PROBLEMS

Colonel Harold's first report¹ as Director of Water Examination to the Metropolitan Water Board is full of interest, for, as he says, he came from the comparative quiet of a peace-time army into the heart of the Board's operations at a time of national emergency arising from two years' drought when it became necessary to consider matters of high policy. London was, however, saved from anything more than anxiety and inconvenience owing to the huge storage systems built up in accordance with the wise policy of his predecessor; and the danger being over Colonel Harold feels free to poke a little fun at the Londoner who talks about a condition of drought when he has sufficient water for all purposes, including a daily long bath. He compares it with the water shortage of an Eastern war-time cantonment, where the daily issue resolved itself into a petrol drum of water, derived from brackish underground sources, receiving the unpurified road washings of an unpaved Eastern town. But the shortage of water in London, such as it was, led to the relaxation of a provision in the Thames Conservancy Act of 1932 that every day 170 million gallons of water must pass over Teddington Weir. This eased the situation, but the reduced flow of the river must have reacted on the condition of the tidal reaches if only to a small extent. At Barking sewage carried upstream by the tide gave rise to many complaints from those using the low tide figure. The minimum statutory flow of fresh water over Teddington Weir of 170 million gallons per day obviously bears to the average volume mentioned the ratio of 170 to 15,700 or 1 to 93. A reduction of 30 million gallons per day in the statutory flow would change this ratio of fresh to tidal water to 1 to 113, a change which could have little adverse effect on the Pool of London. Also it should not be overlooked that some of the extra water abstracted from the river must ultimately reach the Thames.

TASTE TROUBLES

Apart from this special source of complaint London consumers found little to grumble about last year. The complaints reaching the offices of the Board

Metropolitan Water Board, 29th Annual Report by Lt.-Col. C. H. Harold, O.B.E., M.D., D.P.H., London: P. S. King and Son, 10s. 6d.

numbered no more than one three-thousandth of a per cent. of population served. Only half of these were complaints about taste, and again only half were accepted as valid after investigation. Strictly speaking the responsibility at law of the Water Board terminates at its mains—no small liability in itself for there are 7760 miles of them. But in practice all complaints are investigated on account of the light which they may throw on adventitious pollution. During the year definite pollution was twice traced to cross connexions of piping in important buildings. Generally speaking, Colonel Harold says, most of the "The tank room offers great attractions as a playground on wet days and the household storage system is a fertile source of pollution. In one case, where a complaint was made that tap water was unfit for dispensing, inquiry revealed an aggregation of lead, shavings, and oakum left in the pipe by the plumber. Evidently every consumer should demand of his landlord a tap direct off the main for drinking purposes. In periods of high atmospheric temperature complaints of a distasteful taste were sometimes received and later of an earthy taste at the time when a profuse growth of algae dies on the filter beds. But, all in all, London water is no mean beverage, and its palatability may be largely attributed to its moderate hardness. During the year a committee of residents in West Wickham, after wide investigation, concluded that whilst it would be possible for their water to be softened, that would on balance be no advantage to the community.

OZONE OR CHLORINE

But the scientific interest of the present report is greeted as to the choice of the final disinfecting agent in water purification. The drought brought to light defects in the filtration system as a result of which chlorine and ammonia points have been installed in many places as an additional safeguard. The continuous flow of water through storage systems results in an enormous reduction of the bacterial and organic content of the water. Next comes an efficient filter barrier, and finally a chemical process which needs time for effective action either in contact tanks or in the mains before the draw off. The aim of successful water practice is to supply a worked-out weathered water with a composition like the unpolluted natural water, and in contradistinction to campaigning measures chemicals are used only as a makeshift process and as a corrective to counter an emergency. The importance of such an invulnerable barrier is illustrated by an incident at Milwaukee in 1916, when the chlorine was accidentally shut off for several hours and the water was badly polluted for one day. The result of this was 25,000 to 100,000 cases of diarrhoea followed by about 600 cases of typhoid fever with 60 deaths. The choice of final process for London water rests between ozone and chlorine—or rather combinations of chlorine and ammonia, for free chlorine is no longer used. Ozone imparts an excellent finish to water and removes the majority of disagreeable tastes. When it has done its work it leaves nothing behind but oxygen. A water cannot be overdosed with ozone, since the gas is ultimately dissipated. Ozone is increasingly popular in France and has been tried out at one of the Board's works at Barn Elms. But whereas chlorine continues to function as an efficient germicide under the worst possible conditions, ozone requires a filtrate of fairly uniform quality. On the other hand, with ozone the contact period

it non-infectious to monkeys and had in addition been shipped from New York to the west coast. The disease developed well within the period of incubation from the date of known exposure. Critics accept the safety of Dr. Brodie's vaccine, but consider further experience necessary to prove its efficacy. So indeed does Dr. Brodie, who is refusing to supply his vaccine except for properly controlled experimentation.

Whooping-cough

Dr. Louis W. Sauer reported on results obtained with his pertussis vaccine which is now being used extensively by physicians in this country. Dr. Sauer sees no evidence that pertussis vaccine has therapeutic value. However, with vaccine prepared and administered in the Evanston Hospital he had had complete success in prophylaxis. With "authorised" commercial vaccine the success has been less complete as is shown in the following Table.

Three-year Report on Pertussis Immunisation

Authorised commercial vaccine (Sauer's c.c.m.)	Infected.	Exposed		Failures.
		family.	outside.	
Private	475	30	23	5
Health Department .	612	13	50	4
Two orphanages ..	242	23	—	1
Cradle (illegit. infants)	187			—
—	1516	144		10

used be only a few minutes, in contrast with the one after a standard dose of ammonia and chlorine. But then again the longer contact period may provide, and not infrequently does, a completely sterile water. There is a further suggestion, which requires careful examination, that ozonized water after exhaustion of the ozone becomes more susceptible to bacterial growth. Colonel Harold sums up the situation thus. From the consumer's point of view, ozone presents the greater attraction, and if properly applied is an effective sterilant, provided that at all times an absence of breaches in the filter barrier can be guaranteed. On the other hand, chlorine offers an all-round security under every possible condition and is the safety-first of waterworks practice.

AMERICAN PUBLIC HEALTH ASSOCIATION

(FROM AN OCCASIONAL CORRESPONDENT)

More than two thousand fellows, members, and guests of this association were registered at the annual meeting held at Milwaukee, Wisconsin, from Oct. 7th to 10th. This is the largest attendance recorded since a registration fee was inaugurated.

Poliomyelitis

The summer epidemic of poliomyelitis and the resulting popular excitement had their effect upon the programme. The governing council voted the creation of a special committee to confer with the U.S. public health service and to announce to the press and to the public whenever it may be necessary such dicta regarding the administrative control of poliomyelitis as may be calculated to allay panic and quiet or prevent unreasonable agitation. As to whether there is any knowledge to disseminate a difference of opinion was expressed. The epidemiologists state that we know at least as much about poliomyelitis as about scarlet fever. An experienced health officer retorts by saying that if every health officer died to-morrow there would be neither more nor less poliomyelitis as a result. Dr. James P. Leake, senior surgeon U.S. public health service, made an effective plea for the reporting of paralysis whenever it occurs. In North Carolina, where this year's epidemic began (in April), 90 per cent. of cases reported were paralytic. This is a quite unusually high proportion. In New York, where there was an excess incidence though hardly an epidemic, 55 per cent. of the cases were paralytic. This summer gave occasion for the trial on a fairly large scale of the vaccine prepared by Dr. Kolmer and Dr. Brodie. Dr. Kolmer's vaccine is a living attenuated virus. It was given to some 12,000 persons, nine of whom subsequently developed poliomyelitis, eight of them with paralysis. Dr. Kolmer stage of incubation and developed because the vaccine was given too late to produce immunity. His critics, however, are not satisfied that there was no causal relationship between vaccination and pathogenesis. They refuse to regard the living vaccine as safe. Dr. Brodie's vaccine prepared in the laboratories of the New York City department of health is a killed vaccine. It has been given to 8000 persons and one only has developed poliomyelitis. The vaccine given in this case had received three times the treatment needed to make

Unsolicted reports have been received from 58 physicians in 22 different States, the total figures given being 6455 patients injected, 476 exposed, and 81 failures. The high proportion of failures to exposures and the low proportion of exposures to injected are explained on the ground that many of these physicians had no means of knowing of exposures except in such cases as subsequently developed the disease.

Every attempt has been made to ensure that the "authorised" commercial vaccine shall be prepared by exactly the same methods as those used in Dr. Sauer's laboratory in Evanston. Three possible causes of failure were discussed: (1) The warming of the vaccine. At the Evanston Hospital this is not allowed to take place at any time between preparation and administration. In distribution of commercial vaccine over the country uninterrupted refrigeration has not been practicable. (2) Age of administration. Seven out of ten failures occurred in children over 3 years of age. As a result of this observation Dr. Sauer is now recommending that children over 3 years receive a total dose of not less than 10 c.c.m. (3) Use of recently isolated strains. In preparation of commercial vaccines there may be difficulty in obtaining recently isolated strains. Microphotographs were displayed showing the marked changes in morphology undergone by *B. pertussis* in culture.

Mental Hygiene

Dr. Elizabeth I. Adams, of the department of psychiatry, Columbia University, made a strong point for the inclusion of this subject in official public health programmes when she pointed out that psychogenic illness, like tuberculosis, is mainly acquired in childhood and is a family disease communicated by prolonged and repeated exposure. Prof. Grant Fleming, of McGill University, while

accepting the wisdom of proceeding slowly in making additions to the official health programme, encouraged voluntary organisations to place the trail and described as centres around which provincial mental hygiene organisations can be created.

Lay Administrators

In the report of the committee on professional education, the following passages gave rise to much comment and some criticism:

In practice in the United States there have been in the past many non-medical health officers, some of whom have served with such distinction as to demonstrate conclusively that a suitably educated individual, not a doctor of medicine, can administer a health department efficiently and well.

While there are many positions in the field of public health which can well or best be filled by workers well educated in the theory and practice of public health but not possessing a medical degree, the position of administrative health officer, whether of state, city or county, demands in general the possession of medical as well as public health training.

We do not recommend the discontinuance of courses in public health for the education of non-medical persons, but the committee believes that such persons should be informed before entering on a course that their probable field of activity will be curtailed by the absence of a medical degree, and that their chances of succeeding to an important administrative position in the field of public health are not bright.

Young men and women intending to enter the field of administrative public health should be advised to secure a medical degree, specialising as much as possible during the medical course in the various fields of preventive medicine, and adding the special courses in public health at the end of the usual hospital internship. It is from such a group that most may be expected in the coming years.

The remarkable personality and teaching ability of the late Prof. Sedgewick is responsible for a group of highly successful lay public health administrators. It is still uncertain to what extent the non-medical public health officer can win a place for himself in public health administration in this country. Should we choose to specialise in social welfare as well as in public health there is a distinct possibility that his prospects may be brighter than this report would indicate.

The new president-elect is Dr. Thomas Parran, Jun., health commissioner of New York State, the president being Dr. Walter H. Brown, professor of hygiene at Stanford University. New Orleans was selected as the convention city for 1936.

MEDICINE AND THE LAW

Damages for Shortened Life

In *Rose v. Ford*, which came before the Court of Appeal last month, further light was thrown on the change in the law whereby a right to damages for negligence can now survive for the benefit of a dead person's estate. This class of case is of interest as showing the attitude of the courts to the assessment of damages for shortened expectation of life and similar questions. At Birmingham Assizes Mr. Justice Travers Humphreys had to consider the case of a girl who, as the result of a motorist's negligence, was injured fatally. Soon after the accident her leg was amputated; two days after the amputation she died. The judge had awarded to her representative

The Use of Films as Criminal Records

Two days after the decision in *Hauptmann's case* at Trenton in New Jersey (set out in this column last week), an Inter-State conference on crime prevention was held in the same building. It was specially concerned to remove obstacles due to the separate and independent jurisdictions of the several States of America. If a general committee a murder and can slip over the border into an adjoining State, he will probably escape the consequences of his crime. The conference decided that the States would make compacts with one another for the surrender of criminals, the summing of witnesses, and the checking of prisoners released on parole; in effect, the State boundaries would cease to exist. The conference also recommended the adoption of universal fingerprinting throughout all the States and the provision of facilities for interchange of criminal records. One other resolution reveals an interesting element of psychology. It advocated the trial and use of "sound moving pictures" in the identification of criminals. "The New Jersey suggestion is that a film be taken of persons convicted of serious crimes. The usage against a chart of Bertillon measurements. At present detectives see him under these conditions on conviction, but a film record would refresh their memory in later years and might be exhibited in

failure was final. The defence had failed to establish these points and the he was actually cutting someone's throat. The he thought he was merely peeling an apple when the nature and quality of his act—as if, for instance, and (3) that, in killing his victim, he did not know or such diseases he suffered from a defect of reason; which the accused had to establish: (1) that he suffered from a disease of the mind; (2) that because of insanity. Lord Hewart enumerated the three points service, had said that there was no evidence of medical officer of long experience in the prison which rejected the application. Dr. Grierson, a Chief Justice delivered the judgment of the court contended that they were delusions. The Lord were damaging evidence of guilty intent; the defence getting steadily worse. His letters and statements since last February, and that his condition had been It was suggested that Bousquet had not been normal "drunk" boxer would not know what he was about. A witness at the trial had said that a "punch-received in the course of his career as a heavy-weight mentally affected by the blows and bruises he had murder owing to his being "punch-drunk"—i.e., boxer, had been insane at the time of the alleged Bennett, K.C., urged that his client, a professional (in *R. v. Bousquet*, Oct. 14th) Sir Henry Curtis In an application to the Court of Criminal Appeal

"Punch-drunk" Boxer's Plea of Insanity

amputation. The judge at assizes was apparently wrong in thinking that the girl's estate could recover damages on the basis of a normal expectancy of life after the sum of £400 would be enough for those 48 hours. before she died and the judges held that the nominal £500 to £400. The girl had lost her leg only two days Appeal cut down the first £500 to £200, and the second life as a woman with only one leg. The Court of damage she would have suffered in going through the loss of the limb, and £500 for the more remote sentatives £500 for her pain and suffering and for

Cancer of the Uterine Cervix.—Figures are now available of over 1000 cases of cancer of the cervix treated more than five years ago, and some interesting comparisons are possible. Presumably in future years survival tables will be supplied such as have recently been recommended by the League of Nations Health Organisation as a result of the inquiry made by a committee of experts under the chairmanship of Prof. James Heyman. Tables of this sort are now prepared by nearly all research centres.

Cancer of the Uterine Body.—Most centres mention that hysterectomy remains the method of choice for early cases. It seems possible, however, that in the future a combined treatment by radium and X ray may replace surgery except in very favourable cases.

Ovar Cancer.—This section includes reports from two hospitals where one-gramme units are in operation. The Middlesex Hospital states, "The teloradium unit has continued to prove its usefulness. . . . Quite apart from the curative value, which cannot be assessed until after a period of years has elapsed, it is a method of therapy which is more convenient and associated with less danger to the staff than is the case when large moulded applicators are used." University College Hospital point out the difficulty of so arranging the ports of entry that an adequate tumour dose is obtained, and believe that the solution of the difficulty lies in the direction of increased radium skin distance with the corresponding increase of radium element. The survival rate of cases of cancer in the oral cavity treated more than three years ago tends to be disappointing.

Cancer of the Rectum.—An interesting description is given of the technique in use at St. Bartholomew's Hospital for cancer of the posterior wall. This consists of perirectal needles passed through the perineal skin, and an ingenious arrangement of intracavitary radium on a rubber plaque pulled up by means of a tube passed through the colostomy opening. It is generally believed that radium gives negligible results in the treatment of rectal cancer, but although the percentage of survivals is low the figures show that it is possible to cure the condition even when radical operation cannot be performed.

Sarcoma.—One or two cases giving a favourable response to radium therapy are quoted, but the difficulty of accurate diagnosis, and the poor results in the proved cases of sarcoma of bone, suggest that detailed analysis is necessary before any conclusions can be drawn as to the value of irradiating the various forms of tumour derived from the mesoblastic elements.

Biopsy.—Workers at the Bland Sutton institute of pathology at the Middlesex Hospital have been making routine confirmatory diagnoses of the presence of growth, with analysis of the portion of tissue for section has been removed after electro-coagulation of the area, and such material is said to give reasonably good histological preparations. The advantages of this procedure include the following: (1) any possible risk of dissemination of the growth by the biopsy is minimised; (2) it is more likely that an adequate piece of tissue will be removed. Excellent micro-

public cinemas when the man, as sometimes happens, is "wanted" for another serious offence after his release from serving his sentence for an earlier crime. Nor is this all. It is said to be the experience of the police that a criminal, when caught, will sometimes volunteer a frank confession to assist the cause of justice or to relieve his own conscience, yet will afterwards repudiate his confession or will falsely allege that it was extracted from him by "third-degree" methods. The New Jersey police have the idea of using the sound-recording film, along with the ordinary cinematograph film, to record the confession at the moment when the criminal is in the mood to tell his story. If the record can show him making his statement voluntarily, deliberately, and at his case, if it can show the police giving him a proper caution and warning him that his statement may be used against him, and that he must expect no advantages from it, then it may some day be available to negate a sudden and unsupported allegation that the man was "beaten up" or unfairly forced to confess. It may be doubtful whether we shall adopt this idea in England, but the proposal is interesting. The recent Inter-State Conference at Trenton indicates that Americans are at last being stirred to some active step to put down crime. The proposed system of Inter-State compacts to avoid awkwardness on State boundaries will recall the authorities to avoid unfortunate incidents on their boundaries in connexion with motor-ambulances and traffic victims. In America the question of crime in relation to State boundaries could best be solved by Federal legislation. This, however, might require a new amendment of the United States Constitution, and at the present moment Federal intervention in State matters is far from popular.

MEDICAL USES OF RADIUM

The research centres throughout the country to which radium has been lent by the Medical Research Council submit reports this year showing good progress and evidence that much thought is being given to improvements in technique. We select from the reports some items of special interest.

Cancer of the Breast.—The surgical unit of St. Bartholomew's Hospital makes an interesting statement concerning the comparative results of surgical operation and radium implants in the treatment of breast cancer. Examination of the five-year survival rates obtained by very careful follow-up shows that the results for the two methods of treatment are not materially different, being in each case 40 per cent. Since the new form of treatment did not prove superior to the old, it was decided to attempt improvement by combining interstitial radium with surgery, the breast being first implanted with radium needles and subsequently excised. It is hoped that by this autumn a special histological study of 50 cases treated by this method will have been completed, and the next report will contain an account of these. Birmingham General Hospital, where many breast cases are treated radiologically, the Marie Curie Hospital and the Middlesex Hospital, all mention the use of X ray therapy either to supplement or to replace radium, suggesting that all are finding here a satisfactory line of advance.

not exist. But the surplus of useless over useful articles can only be compared, he feels, with the surplus of failures over successes in human reproduction—a comparison which might be a little discouraging to medical authors, did he not also point out that both the fertilising spermatozoon and the fertile new idea would never have appeared if a clean sweep had been made of all germ-cells and all ideas. One of "Brian's" complaints is that the interest attaching to medical articles is too fugitive and ephemeral. Who wants to know that a louse may make a guinea-pig epileptic? It is a matter interesting only the readers of a less degree, the house. He thinks the reader's task would be much facilitated if only the author would condescend to summarise the gist of his paper in a few lines. But a summary is apt to be deservedly banal; the author prefers it only grudgingly, feeling that no summary can do justice to the wit and wisdom to be enjoyed by the conscientious end-to-end reader. The late Dr. Slosson once wrote that 90 per cent. of the manuscripts he had handled in twenty years as an editor would have been improved by cutting off the first page or paragraph. If manuscripts were thus to be handled in rotation by one member after another of the editorial staff of a journal, only the summary might be left, and readers like "Brian" might have their hopes realised and succeed in keeping abreast of the times.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

EDINBURGH UNIVERSITY

Field-Marshal Viscount Allenby was last week elected rector of Edinburgh University for three years, in succession to General Sir Ian Hamilton. The election was accompanied by the traditional fight in the Old Quadrangle. A feature of the election was the support given to Dr. Chalmers Watson by students who sympathise with his views on the reform of the medical curriculum. The voting was carried out on the proportional representation basis, and after the votes for the Marquis of Douglas and Clydesdale and Mr. C. M. Griever had been distributed, the final count was: Lord Allenby, 1017; Dr. Chalmers Watson, 916. At a recent meeting of the university court it was announced that the Rockefeller Foundation had made a grant of £1500 to the department of medical chemistry, to provide for the expenses of Prof. Barger's work in vitamin B₁ for a period of three years from (October, 1935. Intimation was received of the resignation of Dr. A. E. Barclay, lecturer in radiology, and it was agreed to appoint Dr. Robert M^rWhitter to the lectureship in his place.

The future of voluntary hospitals in Scotland was discussed last week at a meeting in Edinburgh of the Committee on Scottish Health Services. It was submitted by witnesses on behalf of the voluntary hospitals that their future depends on the attitude of the State and local authorities towards them during the next five years. Voluntary hospitals had approved the provisions of the Local Government Act, but its working had not been satisfactory. The local authorities had not proceeded on the principle of co-operation. It was urged that the voluntary hospitals should be officially recognised by the State as an essential factor in the health services, and that

Not long ago I wrote about the gesture made by a French medical society, which decided to reduce medical fees by 10 per cent, as part of the national movement towards a lower cost of living. This move has not won all the support it perhaps deserved, and replies to a questionnaire by the Confédération des Syndicats Médicaux suggests that roughly 40 per cent. of the members are hostile to all reductions whatsoever. The remaining 60 per cent. favour some system of reducing charges, but do not agree about the form it should take. It is felt that if the 10 per cent. cut is applied to a 15-franc consultation in a surgery, the doctor will collect a rather ragged sum which includes odd centimes. This is only one of the many little difficulties which have cropped up during the discussions. But while the medical profession has been debating the matter in an academic spirit as could be generated in a rather mundane atmosphere, the Minister of Public Health, Monsieur Laroze, has asked for tangible proof of the profession's willingness to fall into line. He has addressed a circular to the prefects throughout France requesting them promptly to summon the representatives of the local medical societies, and to learn what measures they propose to take to reduce medical charges. References to this action in the medical press suggest that behind the Minister's thirst for knowledge there may be an administrative rod in pickle.

(FROM OUR OWN CORRESPONDENT)

The present wretched quality of French bread was again discussed at a meeting of the Academy of Medicine on Oct. 8th when the Bread Commission presented a report which was a model of plain speaking and an endorsement of the resolution recently adopted by the Pharmaceutical Society of Paris. The Commission duly pointed out that while the farmers are organised in one trade-union, the millers in another, and the bakers in a third, there is no such thing as a bread-eaters' trade-union. This is a great pity not only for the unorganised bread-eaters but also for the said farmers, millers, and bakers, who have long suffered from an unofficial strike of bread-eaters, carried on more or less unconsciously. In an attempt to mend matters the Confédération des Syndicats Médicaux has arranged with the Bakers' Union for the sale from Oct. 20th to Dec. 15th of "bon pain" made of exclusively French flour containing 11-12 per cent. of dry gluten. In each arrondissement of Paris one baker's shop has been selected for the sale of this bread.

FURTHER CRITICISM OF MEDICAL JOURNALS

A correspondent in *Concours Medical*, signing himself "Le Maitre," addresses himself a little plaintively to the弊弊's medical journalism. "The functions of the弊弊's, believes, are to offer authors the opportunity of publishing their views, and to provide printers with a livelihood. All of which is most laudable, but the弊弊's, however, is not to be confounded with a livelihood, and is also unthinkably

a thoroughly representative organisation should be set up to bring them directly and officially into touch with the Department of Health for Scotland. The witnesses stated that the inadequacy of medical attention at home added greatly to their work, especially for children.

This whole subject bristles with difficulties. Local authorities are at present attempting to construct hospital services which will equal those provided by the voluntary hospitals. If the voluntary hospitals are able to maintain their present standard of efficiency, they are likely to remain the centres of the profession in Scotland. It is arguable that the State or local authority should see that the efficiency of the voluntary hospitals does not suffer from lack of funds. Any attempt, however, by the local authorities to control the management of the voluntary hospitals is bound to meet with strong resistance.

VIENNA

(FROM OUR OWN CORRESPONDENT)

FEWER MEDICAL GRADUATIONS

The report of Vienna University for 1933-34 shows

for the first time since the war a distinct and constant fall in the number of students qualifying for the M.D. In 1913-14 the number of female and male students promoted to that degree was 385. When peace returned there was a rush of students whose studies had been interrupted and the figure went up to 521 in 1920, and rose steadily to 743 in 1924-25. After this, for quite a while it remained fairly stationary at about 600. In 1932-33 it again reached 521, and in the following year 442. According to calculations the final figure for 1934-35 will not exceed 420. But already an increase in the number of medical students has been announced again this winter term, for over 1500 have applied for admission to the courses. This is somewhat unexpected, for the lowering of the practitioner's income and general standard of life is so vitally manifest that one would have thought young men would be very unwilling to take up this profession. The only explanation one can think of is that the outlook is just as bad in all the other "intellectual" occupations, and that many a youth, thinking that times may change before he is through with his studies, goes in for medicine because nothing better opens before him in this country.

MARRIAGE AND PROGENY IN AUSTRIA

The Vienna board of health publishes some interesting statistics of the ages of men and women at marriage. A period of ten years has been chosen for fair comparison, and it is found that of all the men married during that period only 0.1 per cent. were under sixteen and 6 per cent. were under twenty. In the age-group 20-25 we find 8 per cent. of the male partners and 25 per cent. of the females. The next five-year age-group, 25-30, shows nearly 50 per cent. of males and 40 per cent. females. Thus pass the thirtieth year of life, and the most favoured age is 25-30 for both sexes. After this the frequency of marriage quickly diminishes, for we find only 1.5 per cent. of men marrying between fifty and sixty and only 0.7 per cent. above the latter age. With the women, the figures were: 0.5 per cent. married

between fifty and sixty, 0.2 per cent. between sixty and seventy, and less than 0.1 per cent. after that. As a rule there is a difference of about five years between the ages of the bride and bridegroom in the favoured periods of marriage: 65 per cent. of all brides belonged to the age-group 20-30, and just as many men in the age of 25-35. Within the last five years the average marriage age has gone up, especially in the rural districts, where as a rule the couples are mostly older than in towns. This is perhaps due to the feeling of the rural population that there is nothing blameworthy in a young woman having an illegitimate child. The parents are in no hurry to marry, and indeed may later marry other partners, no blame being attached to the woman.

The Board of Health's report also gives information about the relative age of parents and children. Of all children 45 per cent. were born within the first ten years of matrimony, and 10 per cent. within the first three years. In 5 per cent. of the births the mother was over forty (no figure is given here for the fathers' age). About 1.5 per cent. of the children had fathers over fifty (the age of the mothers is not stated). It is interesting that 0.5 per cent. of the births took place twenty years or longer after the marriage. The oldest mother within the period of observation was 49½ at the time of her baby's birth, the oldest (supposed) father 72. Altogether the number of couples without children is growing rapidly and alarmingly in the towns, as everywhere in Europe. The decline of the births is over 50 per cent. in the last decade. It may be added here by 15 per cent. so that relatively these are going up.

DEATH OF PROF. PAUL

A few days ago Dr. Gustav Paul, formerly director of the Federal Vaccination Institute, died at the age of 76. He was a native of Prague (then an Austrian city), and soon after his graduation was appointed assistant at the Medico-forensic Institute there. He then served in the public health department of the Ministry of the Interior, and in 1895 took over the charge of the new institute in Vienna for producing vaccination lymph. He was the discoverer of the correct test for the early diagnosis of small-pox, and the modern equipment of the institute and its excellent organisation are entirely due to him. He also originated the therapeutic use of lymph for cutaneous therapy of chronic rheumatism, which is much used in Central Europe.

NEW HOSPITAL FOR ILFORD.—The Ilford council have accepted a tender from the Essex county council for the site of the old Ilford pumping station on which a new hospital is intended to serve Barking and Dagenham, leaving the King George Hospital to provide for the northern area.

KING EDWARD VII. HOSPITAL, WICKSOM.—This hospital is starting a contributory scheme, to which members are to contribute a shilling a week and in return receive a sum not exceeding £28 a year in any twelve months towards the cost of hospital or nursing-home treatment for themselves or for their wholly dependent relatives. So long as accommodation is available they will be received at the King Edward VII. Hospital in the private wards, but if this is not possible they will be able to make arrangements with another hospital or nursing-home. Applicants over sixty years of age will not be admitted, and the scheme does not provide for treatment of any notifiable disease, or for maternity or chronic cases.

PANEL AND CONTRACT PRACTICE

Group Practice in America

The problems of medical practice in America appear to resolve themselves into two: (1) How can medical care be made more efficient and free from fee-splitting and other stigmata of commercialism? (2) How can such care, with adequate remuneration for the doctors giving it, be brought within the economic resources of the poorer members of the community? For the solution of the first problem Dr. Hugh Cabot in his recent book *“Favors an extension of group practice, which is now increasing in America. The first group, and of course the most outstanding, is the Mayo Clinic, which began in 1887, and there are now about 150 groups covering a very wide area. The group includes general practitioners and specialists with laboratory aids working as a medical and financial unit, the fees being paid not to the individual doctors but to the group. There is a growing tendency to extend the facilities afforded by the group to isolated practitioners in country districts, and so enlarge the group's area of influence. The group is in fact an example of evolution by differentiation and integration.”*

The second problem presents, perhaps, more formidable difficulties. Compulsory health insurance has been suggested as a solution, but Dr. Cabot, though alive to the advantages secured in Europe, and especially in this country, by this measure, is doubtful whether it would succeed in America. Fifteen years' experience of prohibition does not encourage him to view with approval any further attempts to impose compulsion on a large scale on the American people. Moreover, he attributes the success of the British health insurance system largely to the fact that it is administered by officers trained in public administration whose appointment and tenure do not depend on political influence, and he can see no adequate body of such administrators in his own country. He favors a development of voluntary insurance, particularly the insurance now offered by some of the groups, an extension of the medical care now provided by many large employers, and a definite assumption by the State of responsibility for the provision of medical care for the indigent—is fulfilled very imperfectly or not at all. He feels strongly that something effective ought to be done, and dissents from the view apparently taken by “organized medicine” in America—the Christian Science view that the difficulties of providing adequate medical care are imaginary, and that the doctors may safely, in the words of Mr. Dooley, “turn the job over to Destiny.”

In other respects too Dr. Cabot's book may well be studied by all who wish to come to a right understanding on the proper relation of doctor and patient in this country, for during the late war he commanded a British base hospital. His recollections go back to the last decade of the last century, the heyday of the family doctor, when people lived in smaller communities, where the local doctors knew every member of the families they attended and acquired a fund of information on family characteristics that was of great help in diagnosis, prognosis, and treatment. He tells how some 35 years ago he assisted at a consultation attended by three Harvard professors.

Conflicting Tribunals

A case noted under this heading (Oct. 19th, p. 920) has had a sequel in the Courts when an action by the father of the deceased girl against the insurance practitioner concerned was heard. The case for the plaintiff ran into part of two days, but the judge stopped the case without calling on the defence as no cause of action had been disclosed and he was satisfied there was no cause for complaint against the doctor. The facts of the case were simple. At 11.30 p.m. on a certain Friday the insured person was suffering with acute pains in her stomach. The pains and vomiting became worse and the services of the doctor were sought some time after midnight. The doctor did not visit the patient but gave the father a small bottle of medicine, prescribing the dose, and indicating that the girl should be seen on the following morning. By 7 a.m. the girl was definitely worse and the doctor was again called. On this occasion he examined the girl and telephoned for an ambulance to take her to hospital where an immediate operation was performed. She died early on the following day, the cause of death being (a) heart failure due to toxæmia, (b) general peritonitis due to (c) perforated duodenal ulcer. The doctor's statement was that he had treated the girl for indigestion and severe constipation a few months previously and thought it was quite possible that she was

after mature consideration had arrived at a favorable prognosis it occurred to one of them to ask the views of the family doctor. “He remarked tersely that the patient was a Jones before she married; that Joneses who showed abdominal distension on the fourth or fifth day of pneumonia died; and that she would die within the week. She did.” But such intimate knowledge of family peculiarities has, Dr. Cabot thinks, become practically impossible in these days with the rapid shifting of population and the increasing reliance of the public on specialists. In America specialism is far more developed than in this country; in some large cities over 60 per cent. of the practitioners are engaged in some form of special practice. In certain quarters this development is deplored as undesirable and unnecessary. The American Medical Association have apparently accepted the proposition “that more than 80 per cent. of all the ailments for which people seek medical aid can be treated most cheaply and most satisfactorily by a family physician with what he can carry in a hand-bag.” From this proposition, or dogma as he calls it, Dr. Cabot dissents; it seems to him to clothe the overworked general practitioner with powers beyond the capacity of the human mind. He thinks that the immense advances in knowledge and technique of the last 20 years have made specialist services necessary over a very wide field, which is likely to expand with further advances. He is, however, aware of the evils of specialism under commercialised conditions of practice, which, it appears, is prevalent in some parts of America. Dr. Cabot tells of a questionnaire on the subject addressed to 105 doctors, not members of the local medical society, of whom 57 replied that they were in favour of fee-splitting, and 48 that they were against it. He thinks the practice is increasing and that the profession must either destroy it or be content to be destroyed by it.

1 The Doctor's Bill. By Hugh Cabot, C.M.G., M.D., a senior consulting surgeon in the Mayo Clinic, New York: Columbia University Press, 1935. Pp. 313. 15s.

such applications. For instance, the Joint committee in view of the fact that they have no right to refuse and see the patent early on the following morning. In some cases, the committee is so small that it is difficult to get a quorum. The father did not suffer from a similar attack. The father did not in any way convey to him the impression that his daughter was seriously ill, and appeared quite satisfied when he left the house with the medicine. According to the doctor he told the father that he would call and see the patent early on the following morning.

On and Off the Medical List

An insurance practitioner whose name was removed from the medical list of an insurance committee as from a date in 1924 now desires to secure readmission to the list in another area. He has applied to the Minister of Health for the restoration of his name, and in accordance with custom the Minister has invited the views of the insurance and panel committees before he accedes. The doctor has produced testimonials on his behalf from medical practitioners have informed the doctor accordingly.

Gi

A Kentish doctor who was surcharged 10*l.* for the supply of 1 oz. of gin in mixture to an insured person has appealed against the decision. In entering her appeal she submitted that the mixture supplied is a recognised formula in the treatment of insomnia in cases of pulmonary tuberculosis. The insurance committee have informed the panel committee that in their view the order for gin was not necessary, inasmuch as it was open to the doctor to order an official preparation which would have produced a similar effect.

PUBLIC HEALTH

Puerperal Pyrexia

"The decision taken nearly ten years ago to make puerperal pyrexia compulsorily notifiable was bound to bring several administrative problems in its train. For the first time a symptom rather than a disease was included in the list of conditions which must be notified to the medical officer of health, and this has not yet been fully realised by many practitioners. The definition of puerperal pyrexia as contained in the P.H. (Notification of Puerperal Fever and Puerperal Pyrexia) Regulations, 1926, is quite clear and cannot be too often emphasised; it is—

"any condition (other than puerperal fever) occurring in a woman within 21 days after childbirth or miscarriage in which a temperature of 100·4° F. or more has been sustained during a period of 24 hours or has recurred during that period."

The practitioner is not required to make a diagnosis as to the cause of the fever; the fever by itself renders the case notifiable.

The question is immediately asked: "Is notifiable pyrexia limited to the puerperal period?"

No. 51, 1934).

The patient is situated "within which (the notifying practitioner) is attending such woman." This was done in order to correct the anomaly of cases being primarily notified to the medical officers of districts far away from where the confinement took place and infection occurred, and it covers such cases as the large group who are confined in central institutions out of the area in which they reside and those who "go home to mother" for their confinement. An exception was made in the case of London, where cases arising in a hospital must be notified to the medical officer of the borough from which the patient was brought into the hospital. This was done in order to abolish the previously existing discrepancy between notification of puerperal fever and puerperal pyrexia. Cases which are brought into a district for treatment in a hospital after notification elsewhere, like all other notifiable infectious diseases, should not be re-notified or included in the returns of the district (R.G.'s Circular No. 51, 1934).

area "with which the place of residence of the ward blocks. The extension provides for a main corridor with seven 54,400 have been accepted by the asylum committee. Plans for an extension to this hospital which will cost £12,000 have been accepted by the asylum committee. FIRE AND KIBROSS JOINT ASYLUM, CUPAR.—To whom should notification be made? The rules governing this were altered somewhat by the amendment regulations of 1928, in which the original notification to the medical officer of health of the area "with which the place of residence of the ward blocks. The extension provides for a main corridor with seven 54,400 have been accepted by the asylum committee. Plans for an extension to this hospital which will cost £12,000 have been accepted by the asylum committee.

CORRESPONDENCE

THE INDEPENDENT MIDWIFE

To the Editor of THE LANCET

Sir,—All who are interested in the practice of midwifery will thank you for the informed and sympathetic leading article on the independent midwife which was published in your last issue. The wife were emphasised in the report of the joint Council, to which reference is made in your article, and the data given by Lady Forster in her *Lyness-Clinton* lecture furnish convincing proof of the severity of these difficulties. Notwithstanding the drive to hospital which has been going on in recent years, domiciliary midwifery is still, and will probably remain, the basis upon which an organised maternity service must be built up. Midwives attend approximately 60 per cent. of all confinements in this country, and their work is done almost exclusively in the homes of the industrial classes. They therefore constitute a highly important unit of the maternity service as it exists at present, and it is an interest, not only of the medical profession, but also of the public, that their work should attain a high degree of efficiency. Midwives who are working under conditions of economic hardship, or even as we now know of actual privation, cannot give of their best, and it is unquestionable that suitable measures to improve their lot are long overdue.

Recent utterances of the Minister of Health suggest that the Government intend to establish a salaried service of midwives; this will provide full employment, adequate emoluments, and security for those who enter it. Unfortunately the number of midwives practising is considerably in excess of the number actually required; consequently a choice will have to be made and those who do not enter the salaried service will, if they remain in practice, be exposed to the existing economic difficulties. The problem of how to improve the lot of this remainder is both complex and difficult. It should, however, be borne in mind that not all of them are entirely dependent for a livelihood on what they earn as midwives. An unspecified proportion of them are "part-time" midwives, who have other means of support, and sometimes follow other occupations when not actually engaged in maternity work. There is much to be said for the view that a midwife's work should always be a "whole-time" job; she will not do her best unless she is in it heart and soul, nor can she maintain her professional efficiency if there are long or frequent intervals in which her attention is turned to other pursuits. There is reason to believe that many part-time midwives turn to other occupations because they cannot get enough cases to earn a livelihood, but many others are part-time midwives from choice, and take cases only as a means of earning a little extra money when required.

The liberty which midwives now possess to regard midwifery as a subsidiary interest, and not as a serious profession which demands their whole attention, is an anomaly which is detrimental to the interests both of the public and of themselves. It may be difficult to end this anomaly at a stroke, but it is inconceivable that it should remain as a permanent feature of our midwifery system.

I am, Sir, yours faithfully,
T. WATTS EDEN.
London, W., Nov. 14th.

To the Editor of THE LANCET

Sir,—The Midwives' Institute has agreed in principle with the establishment of a service of salaried midwives, but it has always realised that, if such a service is to be successful, the competent midwives now in practice must be retained so far as is possible. The returns for the questionnaire sent by the Institute to independent midwives, and ably reviewed by Lady Forster in a preliminary survey at the *Lyness-Clinton* lecture which you discuss in your leading article of Nov. 2nd, do in fact show that the middle-aged private midwife is the stand-by of the mother, especially in urban areas, and as is well known her records are for the most part excellent.

It has to be recognised that until schemes can be devised to make recruitment to the midwifery service an attractive and permanent profession to young well-educated women, both by regulation of the number of entrants and the provision of a longer and better training, both expediency and justice will be best served by making full use of the most experienced of the present-day midwives. It also needs to be realised that the midwife who is employed as a full-time worker requires adequate pay; her expenses which must be incurred in connexion with her profession are considerable and include the provision of uniform, apparatus, telephone, and suitable domestic help. The Institute is making further detailed inquiry into the cost of these items, but it is certain that the midwife's salary should not, on the above grounds alone, be in any case less than that now given to health visitors; and further, in assessing salaries above the minimum, the greater responsibility of the midwife should be taken into account.

The Midwives' Institute, although it holds fast to the conviction that the midwife must always hold full personal responsibility for her own part of the work, requires the close co-operation of doctors and midwives.

I am, Sir, yours faithfully,
E. M. PEE,
President, the Midwives' Institute,

THE TOXÆMIA OF BURNS

To the Editor of THE LANCET

Sir,—Patients who die during the first four days following the infliction of a severe burn are generally debilitated to that notorious and all-pervading entity known as "toxæmia," the Atlas or Hercules of surgery and midwifery, on whose broad shoulders is placed responsibility for nearly every catastrophic not clearly due to a known deadly agent. With the adoption of the tannic-acid treatment of burns by E. C. Davidson, of Detroit, in 1923, the percentage of deaths in the stage of "acute toxæmia" fell significantly; an improvement ascribed, quite justifiably, to the coagulating effect of tannic acid on soluble protein, resulting in less absorption of some toxic and supposedly albuminous substance dissolved and possibly denatured. It is stated in the *Medical Research Council's* special report (No. 141, p. 10): "No antitoxins (to these toxic substances) are produced." Sepsis, in these cases, is yet to be controlled, as the same report admits in the con-

cluding paragraph: "Further therapeutic advances will follow the lines of simplifying and shortening the methods for inducing coagulation, and of more efficiently preventing and controlling sepsis." In the absence of sepsis, the M.R.C. authorities seem to imply, there can be no toxæmia due to bacteria; the first four days' sickness, they conclude, is too early for any possible bacterial action.

It occurred to me that a proportion of the cases dying of "acute toxæmia" during the four dangerous early days might be accounted for on the assumption that their symptoms were due to the absorption of staphylococcal toxin. This theory I have not yet had the opportunity of testing on any effective scale, but I think it worthy of consideration. One case of an adult whom I had treated for an independent condition with a long course of staphylococcal toxoid injections fell and was dragged while playing polo and sustained a very extensive graze, including the skin over nearly the whole of his back and shoulders. This healed without any signs of sepsis or toxic absorption—a most unusual result. More important, Prof. R. Cruickshank (Jour. Path. and Bact., Sept., 1935, p. 367) found *Streptococcus hemolyticus* in the skin of half his burn cases on the second day; *Staphylococcus aureus* was also frequently present, and *Staph. albus* in 56 per cent. of cases on the first day. Staphylococcal toxin can be produced in the body very rapidly, and its effects may not be preceded by any display of "sepsis," as the Bundaberg disaster taught us. I suggest that every case of severe burn should receive intravenously, at the earliest possible moment, an injection of staphylococcal antitoxin amounting, for an adult of normal size, to at least 5000 international units. I believe it is the practice in some hospitals to give staphylococcal antitoxin prophylactically; the staphylococcal antitoxin could be combined with this.

People constantly exposed to the risk of sepsis, by nature of their employment, could be treated prophylactically with a course of staphylococcal toxoid injections.

I am, Sir, yours faithfully,

FRANK MARSH.

BREATHING EXERCISES IN ASTHMA

To the Editor of THE LANCET

SIR,—My attention has just been called to an article by Dr. J. L. Livingstone in THE LANCET of Sept. 28th entitled the Value of Breathing Exercises in Asthma. I feel bound to add from first-hand knowledge some facts to his account. I was chairman of King's College Hospital from 1929 to 1933; as over a long period of years Miss Seyfang had effected complete and lasting cures for asthma for many of my relatives and friends by means of breathing exercises, and as she was perfectly willing, indeed anxious, to place the exercises that she had devised into a system after years of study and training at the disposal of the medical profession, I suggested to Dr. Livingstone that she should work in the Asthma Clinic at King's so that her methods could be observed and the results tabulated. This was arranged, and as a consequence Dr. Livingstone told me himself that he had never before seen anything to approach the successes obtained by the exercises. Unfortunately in arranging for their extension he took the view that no training was necessary in them for the giver. They were incorrectly given in con-

sequence, and as any failure would then have been attributed to Miss Seyfang's system she, with my approval and indeed at my advice, ceased to give her services. She had given them for nearly two years on a purely honorary basis and with undisputed success. Dr. Livingstone says in his article "differed only in detail" from those already known. I cannot recall that any breathing exercises for asthma were successfully used at King's before her advent, and in any case surely that remark is equivalent to a practitioner saying that he knew that a certain cure was good for a certain disease but that he did not know, in detail, what the prescription should be. Miss Seyfang has never complained of the ungenerous treatment she received, but has continued her extremely successful work in her own clinic, and has earned the lasting gratitude of all who have been to her.

I am, Sir, yours faithfully,
GORELL.

QUININE AMBLYOPIA

To the Editor of THE LANCET

SIR,—As cases of quinine amblyopia are rare in this country, the enclosed picture of the left fundus of a patient's eye may be of interest to some of your readers. The disc is atrophic, and some of the arteries have become thread-like, while the visual fields were contracted peripherally. In spite of these changes, after a few injections of strychnine, the patient got full vision with glasses for a small amount of myopia.

The patient was seen for Dr. G. Hume (who was away), and the history was that after being away from white people for two years, doing administrative work among natives in Africa, he developed obsessions and, being invaded home, tried to end his life by taking 60 grains of quinine. He went blind and deaf, but when I saw him sight and hearing had somewhat recovered. He was 26 years of age. The cerebro-spinal fluid was normal, but the blood gave a very faint Wassermann reaction, which was not confirmed later. As the fundus, visual fields, and history are typical of quinine poisoning, and there were neither history nor signs of syphilis, that can be excluded.

My friends in the tropics tell me that 15 grains of quinine sometimes make patients uncomfortable. My chemist-patients and friends here tell me that women try it as an abortifacient, but generally get frightened and give it up on the first signs of giddiness, headache, dizziness, or interference with their sight—symptoms which may be produced by doses of 15-30 grains.

I am, Sir, yours faithfully

Harley-street, W., Oct. 29th.

SYDNEY TIBBLES.

radiograms may however show points of great importance in suspected malignant conditions—e.g., the presence of encapsulation and of metastases in the axilla. The detection of metastases in rib is mentioned, but these must be rare in cases which still present any difficulty in diagnosis. It is claimed that X ray examination gives information which would in its absence be obtained by repeated palpation, a procedure believed by many to involve the risk of disseminating malignant cells in the lymphatics. Even though the diagnosis of malignancy at a really early stage remains unsurmountable without histological examination, in doubtful cases X ray examination may offer some support to a diagnosis, positive or negative, founded on clinical signs. In women over forty, moreover, the presence of well-marked mastoplasia or cystic disease is in any case coming to be regarded as an indication for local amputation, and radiological evidence that such a condition is actually present allows the clinician to advise operation with more confidence. In cases of abscess of the breast it may be useful to ascertain the size and extent of the lesion. In malignant tumours the demonstration of axillary metastases at a palpable stage must lead to careful consideration of the rival claims of operation and radiotherapy. It follows that even in cases where the diagnosis is not in doubt there is something to be said for investigation of the tumour by X rays. The reproductions of the radiograms selected by Ritvo and his colleagues to illustrate their article suggest, however, that their interpretation may be a difficult matter even for the expert.

THE COURSE OF RHEUMATIC HEART DISEASE

THE natural history of a chronic disease such as rheumatic fever is difficult to ascertain with any precision. It is known to be a disease of which the initial manifestations occur mostly among school-children or young adults, and to leave permanent cardiac lesions which shorten life. The only way to determine the common course of the disease is by following a large number of cases from initial infection to death, an arduous task which has been accomplished by A. C. De Graff and C. Ling,¹ working in New York. They noted in a group of 644 patients the average ages of onset of important phases of the disease, notably initial infection, 17 years; first symptoms of cardiac insufficiency, 28 years; first appearance of heart failure, 30 years; death, 33 years. Thus the average patient had an economic life of only 11 years—the period between first infection at 17, and the first symptom of diminished circulatory reserve at 28.

The records of this same group of 644 patients were analysed to discover how the course was affected, if at all, by the various valve lesions. The effects proved to be slight; but in the presence of tricuspid or pulmonary lesions, and also with isolated mitral insufficiency, the outlook was slightly less favourable than with other valve lesions. The addition of aortic incompetence to mitral stenosis had no effect on prognosis as compared with mitral stenosis alone, though cases of aortic lesions alone were at a slight disadvantage in comparison with mitral stenosis. The incidence of congestive cardiac failure was high, being higher the greater the number of valves affected; with aortic lesions alone, more than one-third of the patients escaped it. The conclusion drawn from these results is that valve lesions are of very little importance in prognosis. De Graff and Ling have also tried to estimate the

influence of auricular fibrillation on the course of rheumatic heart disease. Among these 644 fatal cases this arrhythmia had occurred in 43 per cent., and a comparison of the cases with and without fibrillation is interpreted as showing the irregularity, per se, to have no effect on prognosis. It is a complication of a late stage of the disease, and when it shows itself the course of the disease is nearly run. According to this view auricular fibrillation is the result of long-standing cardiac lesions, but does not cause any further appreciable impairment of the circulation.

PYURIA IN CHILDHOOD

THE apparent increase in the incidence of pyelitis in childhood is a phenomenon which many experienced physicians have observed without being able to explain. E. Holzmänn² has recently made some observations which may provide a clue. Though pyuria is not usually considered to have any close association with infections of the upper respiratory tract, the part played by tonsillar disease in the aetiology of nephritis is clearly recognised. Droplet infection of the upper respiratory tract is regarded as the most important source of disease in childhood. Holzmänn records instances of pyuria definitely associated with acute tonsillitis, and also reports one case in a girl of 6 years where removal of the tonsils caused the prompt disappearance of a chronic pyuria. He also comments upon the duration of attacks of pyuria, claiming to have collected evidence in support of the theory of a seven-day cycle. In children the tendency for a febrile illness associated with pyuria to come to an end on the seventh, fourteenth, twenty-first, or twenty-eighth day of illness has, according to this view, to be considered before any special medicament is given the credit for effecting a cure. Throughout Holzmänn's paper he is careful to use the term "pyuria" without any closer designation of the underlying pathological process present, and he does not indicate the amount of pus in the urine that would in his opinion justify the diagnosis. A. B. Helper and R. T. Scott have recently³ set out to determine what constitutes a pyuria of clinical importance, and what is its significance when it is encountered in an ordinary routine examination. They have investigated the urine of all children on their admission to an orthopaedic hospital over a period of nine months; a voided specimen of urine was examined both before and after centrifuging. If there was pus in any appreciable amount the patient was catheterised and the urine again examined before and after being centrifuged. If pus was then found a full investigation of the genito-urinary system was then carried out. Nearly 700 children came under review, and the first fact of importance discovered was that pus cells could be demonstrated in 99 per cent. of the ordinary voided specimens of urine after this had been centrifuged. Catheterisation reduced this number to 13 per cent. Altogether 66 children were detected by this means as having pyuria in need of a fuller examination; 26 of them were found to have disease of the urinary tract such as hydronephrosis, congenital valve of the urethra, and neuromuscular incoordination of the bladder mechanism; 13 of these having pus cells in the urine only in amounts well under what is quoted in the literature as a "normal" pus content. It is suggested therefore by Helper and Scott that the amount of pus present is no guide as to the necessity for cystoscopy or other forms of examination. In children with similar

¹ Amer. Heart Jour., 1935, x., 459 and 630.

² Dent. med. Woch., August 23rd, 1935, p. 1352.

³ Jour. Amer. Med. Assoc., August 17th, 1935, p. 499.

lesions, counts per high-power field in dry preparations varied between 1 and 20. Since many of the congenital anomalies of the urinary tract are "silent" in the early phases it is urged that it is a greater error to ignore a few pus cells in the urine than to submit a child with such a slight degree of pyuria to an unnecessary series of tests. The study also serves to emphasise the need for catheterisation before any real significance can be attached to the presence of pus cells in the urine. Even in boys, after thorough cleaning of the glans and prepuce, evidence of contamination was encountered. It is also clear that much of the disagreement in the literature as to what may be regarded as the normal number of leucocytes or pus cells in the urine is due to varying methods of collecting and examining specimens. Pending agreement upon what constitutes a pyuria the main deduction to be drawn from the study by Helper and Scott seems to be that the presence of even a few pus cells calls for careful scrutiny of the whole clinical picture.

TEST FOR THE COMPETENCE OF THE LUNGS

No surgeon would think of removing a kidney without first satisfying himself of the efficiency of the one he would leave behind. The increasing popularity of artificial pneumothorax and the more permanent ways of producing pulmonary collapse are directing attention towards the functional efficiency of the lungs. Bronchial spirometry,¹ however, which is similar in principle to catheterisation of the ureters, has not yet found practical application in this country, largely because of its technical difficulties. In looking for an alternative means of measuring respiratory efficiency Dr. Bluhm, of Söderby Hospital, Sweden, has considered both basal metabolic rate and blood circulation through the lungs; but the former he finds to be unaltered in patients with pulmonary tuberculosis, even in the presence of a slightly raised temperature or after unilateral or bilateral collapse, while the latter is affected only by gross destruction of pulmonary tissue and not by pneumothorax or thoracoplasty. The "working test" for pulmonary efficiency, which he describes in a monograph² depends on the comparison of oxygen-consumption at rest with oxygen-consumption after the performance of a standard amount of work, and is based on the technique which Nylin has used for testing cardiac function.³ The subject of the experiment ascends flights of steps placed in a circle for 20 rounds (occasionally only 10), the rate of walking being fixed by a metronome at 88 steps a minute. The relative oxygen-debt (Leonard Hill) is equivalent to the increase per minute in oxygen-consumption following the period of work. Normal persons sometimes show little or no increase, but most results lie between 10 and 25 per cent. Bluhm's pathological material consisted of 102 patients on whom 411 determinations were made; the vital capacity of each was also taken, but it showed little or no correlation with the functional test. The first group of tuberculosis patients comprised those not treated by any form of collapse therapy: the majority showed a normal oxygen-debt; some gave higher figures and a good correlation was established between the oxygen-debt and the amount of lung tissue involved. Exudative cases on the whole showed better functional efficiency than productive ones.

In the second group consisting of pneumothorax cases it was found that when a considerable amount of lung tissue was put out of action the oxygen-debt tended to reach higher values, especially when the pre-existing disease of the lung had led to fibrotic changes. In such cases the functional efficiency of the lung is less after a refill than it was before. In general, insufficiency tends to appear in productive cases when pressures exceed plus 1 cm. of water, whilst in exudative cases plus 3 may be reached without any functional change. Altogether 77 per cent. of pneumothorax cases showed a raised oxygen-debt. The patients investigated included only 8 who underwent thoracoplasty and in only 4 of these were observations made both before and after treatment. Three cases of phrenic evulsion are also included, but the data are too scanty to justify any conclusions. Pleural effusion complicating pneumothorax was several times associated with a particularly high oxygen-debt; this is probably due partly to the increased collapse of the lung from the weight of the fluid and partly to fibrotic changes in the pleura spreading into the lung.

That this test for lung function may have practical value is suggested by the results of a follow-up of 38 cases which show a fairly close correlation between the results of the functional test and the subsequent capacity for work. The thoracoplasty cases are few in number but show that, although the vital capacity is greatly reduced by thoracoplasty, there may be a normal or only slightly increased oxygen-debt associated with full working capacity. If further experience confirmed the results described in Dr. Bluhm's monograph, we should have a useful adjunct to clinical judgment in deciding on the advisability of surgical collapse. Oxygen-debt, however, depends essentially on muscle metabolism and slow changes in the blood, so that it is doubtful whether it really bears any relation to pulmonary efficiency. Hence it would have been useful to have observations on controls with various disorders of the heart and lungs. A further objection to the test is that it cannot be used for people who are confined to bed.

CYCLOPROPANE

THE latest account of cyclopropane strengthens the good opinion that has been formed of this new gaseous anæsthetic. Writing from the Lahey Clinic at Boston the authors¹ record only 184 inhalations but are able to provide much instructive information, including an important warning that "in using cyclopropane, where we know that the anæsthetic mixture is not only inflammable but explosive as well," particularly searching care should be taken. They think the special value of the gas lies in its application to thoracic surgery, and of their 184 operations no less than 124 were on the chest. A carbon dioxide absorption technique is of course regarded as essential for the use of cyclopropane in practice, and with this method they have maintained surgical anaesthesia at the rate of about a gallon an hour. This brings the gas within reasonable limits of expense. The utmost care is needed to avoid leakage by making the face-piece really airtight. Cyclopropane is solvent for rubber and rubber compounds; hence the pin type of valve is best adapted to the use of this gas. The solvent action however is not manifest in concentrations low enough to be within the anæsthetic range, and ordinary tubing and breathing bags, and even flutter

¹ Sise, L. F., Woodbridge, P. D., and Eversole, U. H.: *New Eng. Jour. Med.*, August 15th, 1935, p. 303.

² Bluhm, I. L.: *Working Test as Clinical Method for Determining the Function of the Lungs*. Acta Med. Scandinavica, Suppl. Ixx, Stockholm, 1935, Pp. 299.
³ Acta Med. Scandinavica, 1933, Suppl. Ili; see THE LANCET, 1933, II., 369.

valves of rubber, can apparently be retained without suffering damage. It is pointed out that "those who begin the use of cyclopropane should bear constantly in mind its great power and its rapidity of action. The effects of higher concentrations are simply astounding and are unbelievable to those who think in terms of the weaker gases, nitrous oxide and ethylene. With these our chief warning comes from signs of anoxæmia. With cyclopropane on the other hand drastic overdosage takes place in the presence of abundant oxygen." At the Lahey Clinic it is held preferable to omit all premedication except morphine gr. $\frac{1}{2}$ and scopolamine gr. 1/100-1/150. Cyclopropane is considered a valuable agent because it combines low toxicity with fairly powerful anæsthetic action. It is obviously an agent whose use requires learning, even by the man experienced with other anæsthetics.

RECENT WORK ON SPERMICIDES

Kölliker's classic work on the physiology of the seminal fluid, which included a study of the way in which the movements of sperms may be influenced by chemicals was published in 1856.¹ Fifty years later Gunther² wrote a paper on sperm poisons. Since then until quite recently, little systematic work would appear to have been done on spermicides. Results of tests have been published from time to time in Germany, America, Japan, Russia, and this country by such workers as W. Steinhäuser, M. Rodecure, Helen Holt, S. Uchigaki, C. I. B. Voge, and J. R. Baker, but, with the exception of Baker, none of these workers has made anything like a systematic study of the spermicidal power of pure substances, nor has an attempt been made to evolve satisfactory laboratory tests that make it possible to compare the spermicidal power of any one pure substance or commercial product with that of any other. A clinical test would be best, but this is not feasible owing to the large number of unknown factors involved. Dr. Baker has been working on chemical contraceptives under the auspices of the Birth Control Investigation Committee, and he has recently described his investigations in a lecture delivered before the Eugenics Society reported in the *Eugenics Review* for July, 1935 (p. 127). He has been at great pains to perfect his technique and to make the conditions under which substances are tested approach as nearly as possible to those under which they would be acting in vivo without sacrificing scientific accuracy. Details of the tests have been published in the *Journal of Hygiene* during the last few years, the last article appearing in the January 1935 issue. He has also tried to discover a harmless chemical contraceptive more efficient than those on the market. Among his observations is that sperms, from species as far distant from each other phylogenetically as the sea urchin, the guinea-pig, and man, react in an almost identical manner to the same chemicals. Rather surprisingly the only inorganic salt which he has found with a high spermicidal power is mercuric chloride with a killing concentration of 1/256 per cent. Acids he describes as weak spermicides, and he points out that, contrary to common belief, substances which are strongly germicidal are not necessarily strong spermicides, and vice versa. No alkaloid tested by him has proved to be a good spermicide; in fact strychnine hydrochloride in certain concentrations has a stimulating effect on the activity of sperms. The most highly

spermicidal substances that he has so far discovered have been aldehydes, phenols, and quinones, the four most spermicidal all being quinones, with toluquinone heading the list with a killing concentration of 1/512 per cent. When one compares this with quinine or chinosol, which can only claim a killing concentration of $\frac{1}{4}$ per cent., it is astonishing that these chemicals have for so long been popular among manufacturers of chemical contraceptives. Dr. Baker emphasises the need to put any possible spermicide through stringent tests for harmlessness, a slow but essential process, before it can even be considered for clinical trial. Dr. Carleton is doing this important part of the work at Oxford. He uses the bitch as his experimental animal and places a known quantity of the substance to be tested into the vagina every day for 28 days. After this the animal is killed and the vagina examined macro- and microscopically for any sign of infiltration or damage to the epithelium. Dr. Baker notes that he and his wife while in the New Hebrides came across some herbal preparations used by the native women, who claimed that certain plants growing on the islands when taken by mouth acted either as contraceptives, temporary sterilisers, permanent sterilisers, or abortifacients. They succeeded in obtaining the seeds of some of these plants and brought them to England where they are being grown under suitable conditions and will be tested on mice.

WEEK-END POST-GRADUATE COURSES

WEEK-END post-graduate courses at or near the opening of the autumn session of the London medical schools are now firmly established as an annual event. The scheme originated at St. Mary's Hospital in 1922, was an immediate success, and after a year or two was gradually adopted by other teaching hospitals. We observed 12 years ago,¹ when reporting the second week-end course to be held at St. Mary's, that the general adoption of a scheme of this sort might go some way to meet the reproach that the London medical schools have little to offer the former student. This year 8 of the 12 schools are providing week-end courses in September, October, or November, 3 of the courses being open to all medical practitioners and 5 confined to former students. Of the remaining 4, St. Thomas's and St. George's organised such courses in the autumns of 1932, 1933, and 1934, and St. Bart.'s again had a successful mid-week course (three days) in June, 1935, this timing having proved popular in recent years. Guy's seems to be the only London school to have consistently resisted the prevalent custom of providing annual refresher courses of brief duration. Although the necessarily intensive and high-speed nature of these courses suggests, as Dr. Robert Hutchison once said, a continuous variety programme, and may conduce to mental indigestion, there can be no doubt of their popularity with the general practitioner for whom they are primarily intended. The subjects of the lectures given during the last few years afford an interesting index of what, in the opinion of the teaching staffs of the great hospitals, are at the moment matters of importance to those engaged in general practice. It must, of course, be remembered that the mere titles of lectures in any course do not necessarily provide an adequate conspectus of its content. Many lecturers prefer the discursive method, dwelling on problems and pitfalls in diagnosis or treatment rather than on one or another aspect of any particular disease. Moreover, some of the teaching is given by means of demonstrations at the

¹ *Zeitschrift für Wissenschaftliche Zoologie*, 1856, vii., 201-81.

² *Arch. ges. Physiol. (Pflügers)*, 1907, cxviii., 551-71.

¹ *THE LANCET*, 1922, ii., 805.

bedside, in the operating theatre, or elsewhere, though, unfortunately, the very popularity of the courses must limit the amount of intimate or informal instruction.

Between 1931 and 1934 only five lectures on psychological topics have been given in these courses. In view of our increasing knowledge of mental disorder and the changed outlook on its problems, it is to be hoped that in future years this subject may receive much more attention. The practitioner realises more and more how largely the psychological element bulks in his work and how it may colour or even dominate the picture in cases of undoubted organic disease. Paediatrics has been given a larger share, with some 14 lectures, including two on acidosis. Radium therapy has been thoroughly discussed and demonstrated and the increasing importance of radiology in diagnosis has been suitably stressed. In addition to numerous demonstrations of new methods of anaesthesia there have been several lectures on the use of new agents, such as Evipan. There have been ten lectures on dermatology. Eczema has been chosen as a subject more than once, possibly because it provides a good excuse for a broad and generally informative survey of skin lesions. "Itching" received a lecture to itself one year, and the medico-legal position of dermatitis and Compensation. Another ten lectures were devoted to pathology, using that term in its widest sense. The new work on filtrable viruses and the serum prophylaxis of virus diseases, a matter of urgent clinical importance to the practitioner, have been clearly explained. More than 30 lectures have been given on obstetrics and gynaecology. Many of the aspects chosen have been conventional—uterine inertia, prolapse, haemorrhagia, toxæmias of pregnancy, and so forth; contraception was the subject chosen for two lectures, and the Aschheim-Zondek test has been described at least once. There was one lecture on sterility, but we have no record of any discussion of the pros and cons of eugenic sterilisation which easily deserved a place. Teeth and dental sepsis in relation to medicine and surgery provided two lectures, and venereal disease four. Turning to general surgery, we find some 77 titles which could be classified under this heading. Prostatic disease, from one aspect or another, has been chosen on 6 occasions and 6 lectures have also been devoted to general or special fractures. Other favoured subjects have been thoracic surgery (4), the surgery of the sympathetic (4), and varicose veins (3). There are no notable omissions in this sphere and the important new developments in neuro-surgery have not been neglected. The surgery of the special departments has also received a reasonable share of attention, mainly on general lines. On ophthalmology there have been 7 lectures, including only one on conjunctivitis and iritis, and in one of the 11 lectures on oto-rhino-laryngology, naso-pharyngeal sepsis in relation to chronic bronchitis and emphysema was discussed. There have been 7 lectures on neurological and nearly 100 on general medical topics. Of the latter, the favourites appear to have been toxic goitre, unexplained pyrexia (a hardy annual), the anemias, diabetes, nephritis, pulmonary tuberculosis, and dietetics. Nobody will quarrel with any of these, but it may have been a little depressing to practitioners that only 3 of these 100 lectures were devoted solely to the subject of treatment. Endocrinology, also, surely deserved more than 2 lectures and allergy more than one.

A week-end is certainly too short a time to do

much more than renew old contacts, but the stimulation that such contacts have afforded and the realisation that certain theoretical advances have an unsuspected practical bearing, have certainly brought to many doctors, senior as well as junior, a refreshment which has lent a renewed interest to their daily work. Some of the lectures in this year's courses, of which particulars are set out week by week in our Medical Diary, will be summarised in *THE LANCET*, three of them in our present issue. It is clear that all those responsible for drawing up the programmes for these quite independent courses have tried to put their audiences into touch with recent work without forgetting that "common things are common," and therefore deserving of attention.

SPAHLINGER BOVINE VACCINE

Hore deferred was making the heart very sick about the Spahlinger human remedies some four years ago, but it was then reported that calves on a Norfolk farm had been successfully immunised with a single dose of simplified bovine vaccine provided by Mr. Spahlinger. At that time veterinary surgeons were satisfied that the vaccine had conferred on calves a high degree of resistance against tuberculosis. A little later a test was begun in Northern Ireland under the direction of the Ministry of Agriculture, using a bovine vaccine prepared according to a method described by Mr. Spahlinger in our own columns (*THE LANCET*, 1932, i., 309). A number of calves which had passed the double intradermal test were divided into two groups, of which one was vaccinated by Mr. Spahlinger himself in December, 1931, with this new bovine vaccine by various routes. A year later a report of the test by three veterinary surgeons attached to the Ministry of Agriculture in Belfast showed that all the vaccinated animals had remained clinically healthy after receiving a dose of tubercle bacilli which killed the majority of the controls within two months. A final report by the same officers on this interesting experiment was issued by the Government of Northern Ireland on Tuesday, from which it appears that eleven vaccinated calves resisted the injection of the test dose of tubercle bacilli in a very similar manner. One animal weakened by nematode infection died of tuberculous meningitis after 607 days. The other ten animals, which remained perfectly well, were slaughtered in the municipal abattoir 780 to 892 days after injection of the test dose. One of them was found to have a tuberculous udder. Post-mortem examination revealed the presence of nodules in the lungs and certain glands; when incised these were found to contain an oily pus-like or cheese-like substance in which tubercle bacilli were not demonstrable by the *Ziehl-Neelsen* method. The material into which the vaccine was injected contained no viable tubercle bacilli. These vaccinated animals had also been exposed for two years to the risk of natural infection and the heifers were put to the strain of calving and lactation. In a foreword to the report, the secretary to the Ministry points out that the highly satisfactory nature of the results raises the question of the compulsory use of the vaccine as a means of eradicating bovine tubercle from the herds of Northern Ireland.

Prof. R. A. Fisher, F.R.S., will deliver two lectures on eugenics and national health at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C., on Oct. 16th and 23rd, at 4.30 p.m. Prof. M. Greenwood, F.R.S., will take the chair at the first lecture.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LXXI.—PROGNOSIS IN PAPILLOMA OF THE BLADDER

PAPILLOMA of the bladder, like papilloma elsewhere in the body, must be regarded as a precancerous growth which is only too likely to become malignant if left untreated. Hospital statistics appear to indicate that the disease is on the increase, but the truth probably lies in the fact that the more frequent use of the cystoscope in cases of hæmaturia has led to accurate and earlier diagnosis. It is not possible to give a prognosis which is applicable to all cases, for it depends on the number of growths, their character, their size, their situation, and the age of the patient, but it can be stated quite definitely that though the recurrence-rate at the present time is high, the prognosis as regards life is good *provided* the patient submits to cystoscopic examination at regular intervals during a period which in the writer's experience cannot be definitely fixed but which should never be less than three years.

In a series of 97 cases which have been kept under careful personal observation the recurrences have been as high as 50 per cent. Many of these patients have been examined at regular intervals for from 10 to 15 years, during which time there have been recurrences in some almost yearly and in others at intervals of one or more years.

The following examples from this series point to the danger of too optimistic an outlook as regards freedom from recurrence, and to the necessity of regular examination over a long period.

Sex and age.		
A. B. . .	M. . .	Frequent recurrences 3 yrs.; free 3 yrs.; one recurrence 7th yr.; free 3 yrs.
C. D. . .	F. . .	Frequent recurrences 1st yr.; free 2nd yr.; recurrences 3rd, 4th, 5th, and 6th yrs.; free 7th yr.; recurrence 8th yr.; free 9th to 12th yrs.
E. F. . .	F. . .	Frequent recurrences 1st yr.; free 2nd yr.; recurrence 3rd yr.; free 4th, 5th, and 6th yrs.; recurrence 7th yr.; free 8th yr.; recurrence 9th and 10th yrs.
G. H. . .	M. . .	Free 7 yrs.; recurrence 8th yr.; free 9th, 10th, 11th, 12th yrs.; recurrence 13th yr.; free 14th yr.; recurrence 15th yr.; free 16th and 17th yrs.; recurrence 18th and 19th yrs.; free 20th, 21st, and 22nd yrs.; recurrence 23rd yr.
I. J. . .	M. . .	Recurrence 2nd yr.; free 5 yrs.; recurrence 8th, 9th, and 10th yrs.; free 11th yr.
K. L. . .	M. . .	Free 2 yrs.; recurrence 3rd yr.; free 4th yr.; recurrence 5th yr.; free 6th yr.; recurrence 7th and 8th yrs.; free 9th and 10th yrs.; recurrence 11th yr.

In three of the above the original operation was transvesical and in three perurethral, so that as far as these particular cases are concerned the method does not seem to have affected the result.

The primary growths are usually on the base of the bladder and close to the ureteric orifices; they seldom occur on the trigone. Recurrences after open operation are often in the region of the scar and in all cases are common in the paratrighal region and occasionally at the internal meatus. In the latter situation the prognosis as regards recurrence is worse, for the growths are liable to be overlooked and are difficult to treat by perurethral methods. When a growth is found on the lip of a ureteric orifice or when recurrences occur repeatedly around it, they should be regarded as possibly secondary to a primary growth in either the kidney or ureter, and every available means of diagnosis should be employed to ascertain if this is correct, for until the

parent growth is removed the recurrences will continue and may spread with alarming rapidity. Also, the parent growth may become malignant while the recurrent growths in the bladder are still benign and are thought to be the sole cause of the hæmaturia. This happened in one of my cases in which a papilliferous carcinoma of the kidney, that probably commenced as a simple papilloma, gave rise to multiple benign papillomata of the ureter and bladder which recurred in the bladder so frequently and in such increasing numbers after ureterectomy, that eventually total cystectomy became necessary.

NUMBER AND SIZE OF GROWTHS

Small solitary growths, provided they cause symptoms which lead to their early detection, seldom give rise to troublesome recurrences as they can usually be destroyed by perurethral fulguration before "seeding" has commenced. Small multiple growths give rise to frequent recurrences, often over a long period, and one of the recurrent growths may become malignant at any time; or benign recurrences may multiply so rapidly as to fill the bladder and cause severe hæmorrhage and severe cystitis. In these cases the prognosis is naturally grave on account of the dangers of ascending infection, of malignancy, and of the surgical treatment (total cystectomy) that may be required. Large solitary growths are always serious, for in addition to their tendency to slough and cause troublesome cystitis they are more prone to become malignant. Further, as removal by the transvesical route is usually necessary, there is the added danger of graft recurrence both in the vesical scar and in the abdominal wall.

FORM OF GROWTH

Five distinct clinical forms are recognisable:—

(1) and (2) The pedunculated or the sessile types of growth with long delicate fronds. These are easily destroyed by perurethral fulguration and the outlook is good provided recurrences are kept in check by regular cystoscopic examinations.

(3) The flat papilloma composed of small compact villi looking like a patch of moss. This also is easily destroyed by diathermy, but if it recurs it should be regarded as malignant and excised.

(4) The growth with coarse tightly packed villi and a thick pedicle. This responds to diathermy less rapidly than (1) and (2), often requiring two or more applications at intervals of five or six weeks, for the slough is slow to separate. On this account it should be regarded as on the verge of malignancy and a guarded prognosis given.

(5) The prominent growth with a finely granular surface. The prognosis is serious, for even if the superficial part is benign the deep layers and base are always malignant.

AGE AS AFFECTING PROGNOSIS

Papillomata are seldom seen below the age of 20 and occur with greatest frequency between 40 and 60. In the young, hæmaturia is usually investigated with little delay, so that a growth if found is always small, generally single, and easily destroyed at one sitting. Recurrence is therefore far less frequent and the prognosis correspondingly good. In older patients hæmaturia is not invariably regarded as serious, being ascribed to "inflammation" of the kidneys, enlarged prostate, gravel, and so forth;

consequently investigation is often delayed for a considerable time, during which the papilloma is increasing in size, is "seeding" and advancing steadily towards malignancy. The prognosis is therefore more serious, for recurrences are more frequent and may at any time be malignant.

The prognosis of aniline tumours occurring in dye workers does not appear to be any different to that of the ordinary growth provided the patient changes his occupation; if he does not do so recurrences are more prone to be malignant.

METHOD OF TREATMENT

Provided the growth is not too large and its whole surface is accessible the best results are obtained by cystoscopic diathermy. This does not of course prevent recurrences, for "seedlings" or implantation growths, too minute to be seen by the naked eye, may be present when the first treatment is given. Recurrences are commonly in the neighbourhood of the original growth but may be anywhere in the bladder and even in the commencement of the prostatic urethra. Therefore at subsequent examinations it is important to inspect the neck of the bladder with a retrograde telescope after the vesical cavity has been examined with the ordinary instrument. When there has been hæmaturia and no growth is found in the vesical cavity the prostatic urethra should be inspected with a posterior urethroscope. In this context it is interesting to note that recurrent growths are unknown in any other portion of the urethra. When the primary growth, though not too large for successful cystoscopic diathermy, is large enough to require several treatments which are either irksome to or unbearable by the patient, an open operation may be considered preferable.

A transvesical operation is only a necessity, when the growth is either too large for cystoscopic diathermy, is not completely accessible, or when it is judged to be becoming malignant. The great disadvantage of an open operation is the danger of graft recurrences. It is estimated from the combined literature that the recurrence-rate after an open operation is 60 per cent. In my series it was 50 per cent. after the open operation and also 50 per cent. after perurethral fulguration. Recurrences are generally in the cystotomy scar where they can be dealt with by perurethral methods and therefore do not add materially to the gravity of the prognosis; but in a small proportion of cases grafts take root in the abdominal wall where they eventually become malignant. The graft may remain dormant for many years and then suddenly light up into a rapidly growing infiltrating carcinoma. This happened in two of my cases; in one 18 months after operation, and in the other after an interval of no less than nine years, when it grew at such a pace that in a few months practically the whole abdominal wall was infiltrated. It is therefore of the greatest importance to watch the patient carefully for several years after an open operation.

DANGER OF MALIGNANCY

Every papilloma of the bladder is a potential malignant growth and the danger of malignancy increases with the frequency of recurrences. In my series of 97 cases 9, or approximately 11 per cent., developed carcinoma; 7 within five years, 1 seven years, and 1 ten years after the first treatment. When the number of primary and recurrent growths these 97 cases must have had is taken into consideration 11 per cent. of malignancy does not seem a very high incidence, but it would undoubtedly have been higher had not the patients been examined at regular

intervals, often for many years, and the recurrences kept in check.

AFTER-CARE

In a series of cases on which this article is based routine cystoscopic examinations were made at the following intervals:—

1st year	..	..	..	three monthly.
2nd year	..	..	..	six monthly.
3rd, 4th, and 5th years	..	..	..	yearly.

If at the end of this period there had been no recurrence the patient was discharged but told to watch the urine and to report immediately should any blood be seen. In the event of a recurrence at any time during the five-year period the routine examinations were recommenced.

There is little doubt that the outlook as regards both recurrence and malignancy depends on frequent and regular cystoscopic examination, for there may be as much as 12 to 18 months' interval between noticeable hæmorrhages, often the only symptom of the growth. This must be impressed on the patient and the necessity for frequent cystoscopic examination explained, otherwise he will very naturally disregard instructions until there is another attack of hæmaturia, by which time the growth may no longer be solitary and may have become malignant.

CYRIL A. R. NITCH, M.S., F.R.C.S.,
Senior Surgeon, St. Thomas's Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. J. E. Clark to *Victory* for course, and to *President* for course; A. L. McDonnell to *Drake* for R.N.B.; and A. E. Phillips to *President* for course.

Surg. Comdr. A. B. Clark placed on the Retd. List at own request, with rank of Surg. Capt.

Surg. Lt.-Comdr. W. P. E. McIntyre to *Resolution*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. A. S. Pearson promoted to Surg. Lt.-Comdr.
Proby. Surg. Lt. A. I. L. Maitland to Haslar Hospital.
Proby. Surg. Sub-Lt. L. Foster to R.N. Hospital, Chatham.

ARMY MEDICAL SERVICES

Col. J. W. L. Scott, D.S.O., late R.A.M.C., K.H.P., from Asst. Dir.-Gen., to be Dep. Dir.-Gen., Army Med. Servs., War Office.

Col. F. Casement, D.S.O., late R.A.M.C., to be Asst. Dir.-Gen., Army Med. Servs., War Office.

Maj.-Gen. R. B. Ainsworth, C.B., D.S.O., O.B.E., late R.A.M.C., K.H.P., having attained the age for retirement, is placed on retd. pay.

Col. W. P. MacArthur, D.S.O., O.B.E., late R.A.M.C., K.H.P., to be Maj.-Gen.

Col. H. M. J. Perry, O.B.E., late R.A.M.C., K.H.S., to be Maj.-Gen. (Supern.).

Lt.-Col. E. M. Middleton, O.B.E., from R.A.M.C., to be Col.

Royal Army Medical College: Maj. Gen. R. B. Ainsworth relinquishes the appt. of Comdt. and Dir. of Studies.
Maj.-Gen. W. P. MacArthur, from Dep. Dir.-Gen., Army Med. Servs., to be Comdt. and Dir. of Studies.

ROYAL ARMY MEDICAL CORPS

Short serv. commissions: Lt. F. J. O'Dowd to be Capt.
Lts. (on prob.) restd. to establt.: J. J. Sullivan, M. Kosloff, and J. L. Gordon.

Maj. J. W. C. Stubbs, D.S.O., M.C., to be Lt.-Col.

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned having attained the age limit of liability to recall, cease to belong to the Res. of Offr.:—
Col. M. H. Babington, D.S.O. (late R.A.M.C.).
Maj. J. A. Bennett.

SPECIAL ARTICLES

THE TRIPLE STRUCTURE OF MEDICINE *

BY WILFRED TROTTER, M.S., F.R.S.

THE constituents of which medicine is made up are readily discernible: they are three—a practical art, an applied science, and an experimental science.

MEDICINE AS A PRACTICAL ART

It is always readily agreed that medicine is an art. The indispensable task of defining precisely what that phrase means is, however, less frequently undertaken. Medicine is a practical art in the same sense as is the work of the farmer, the smith, or the joiner. When this primary stage of definition is reached it becomes clear that definite qualities and modes of activity must be possessed by this element in medicine. These are of great practical importance, and it is surprising that they have had little exact notice. Now that the prestige of science is so high the statement that a great part of medicine still retains the status of an art is often made with a note of apology. Nothing could be less justified by a realistic sense of cultural values. The method of the practical art was the first instrument forged by man for the subjugation of chaos. At the dawn of civilisation the preservation of knowledge was far more important than its discovery. The accidental fruits of experience and the creations of genius could be saved from an infallible oblivion only by being preserved in the precepts and tradition of a practical art. The superlative need for preservation made the arts

* Being the concluding section of the Lloyd Roberts lecture, entitled *General Ideas in Medicine*, delivered before the Royal Society of Medicine on Sept. 30th, 1935.

(Continued from previous page)

Capt. J. V. Dockray, from Supp. Res. of Offr., R.A.M.C., to be Capt.

MILITIA

Maj. H. C. G. Pedler retires on attaining the age limit and retains the rank of Maj.

TERRITORIAL ARMY

Lt. G. G. Farrington to be Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS

Maj. H. A. Playfair-Robertson relinquishes his commn. and retains his rank, with permission to wear the prescribed uniform.

Capt. H. R. R. Mavor, from Active List, to be Capt.

ROYAL AIR FORCE

The undermentioned are granted short service commissions as Flying Officers on probation for three years on the active list with effect from Sept. 2nd, 1935: H. E. Bellringer, C. M. Carlyle-Gall, T. J. M. Gregg, R. S. B. McClean, R. S. Peill, R. L. Soper, W. J. L. Dean, L. N. Trethowan, J. B. Wallace, A. S. Amsden, A. B. Marshall, J. P. Carlile, and S. R. C. Nelson.

Flight Lt. J. Magner is promoted to the rank of Squadron Leader.

Dental Branch.—Wing Comdr. L. Somerville-Woodiwis, to D.M.S. Dept. of A.M.P. Air Ministry, for Staff duties as Chief Dental Officer, vice Group Capt. C. L. Colbran, O.B.E.

D. P. Boyle is granted a non-permanent commission as a Flying Offr.

INDIAN MEDICAL SERVICE

Capt. L. D. Sarronwala and Capt. M. N. Pai relinquish their temp. commns.

inherently conservative; for there was, and is, no unequivocal difference between the change that was progress and the change that was decay. New knowledge was therefore accepted as reluctantly as old custom was given up.

An art carries its possessions in precepts and rule of thumb which are applied to individual cases in the light of a trained judgment. It does not possess principles of general validity automatically applicable; that is the method of applied science. An art is taught first in precepts and rules, secondly in experience of its material, and thirdly—and most important—by example. The method of apprenticeship is thus the keynote of education in the practical arts, because it brings the pupil into familiar contact with his material and gives him the constant example of his teacher in the actual things he himself will ultimately have to do. English medical education has long been recognised as having a characteristic product. This quality, whether we regard it as good or bad, has been due to medicine being regarded as essentially a practical art, and to the consequent predominance of apprenticeship in some form as an educational method.

If we have grasped correctly the nature of the practical arts we shall be able to specify to some extent the attitude of mind and the kind of thinking necessary for the satisfactory practice of them. It is commonly said that one of the chief objects of medical education should be to make the student think scientifically. The saying is perhaps as good an example as could be found of the need in which medicine stands for the exercise of the critical mind. To think scientifically may be supposed to mean one of two things. First, it may signify the adoption of a general habit of thought induced in, and characteristic of, those who practise experimental science. Unfortunately, however, it is not possible to show that the scientific worker outside his job displays more wisdom, insight, and practical judgment than anyone else of the same general capacity. Secondly, to think scientifically may mean to use the kind of mental process necessary for the satisfactory pursuit of experimental science. The scientific worker among other qualities must have an especially severe standard of evidence and proof; he must draw no conclusion that is not strictly justified by the evidence, and he must be content to leave in suspense any decision for which the materials are not quite complete. Now the last thing a doctor is free to do is to exercise the scientific suspense of judgment, and he scarcely ever makes a decision that is justifiable on strictly scientific grounds. The advice to think scientifically would seem, therefore, to risk paralysing his judgment rather than activating it.

The truth appears to be that what the user of a practical art needs is less the strict and limited instrument of scientific method than what may be called a soundly cultivated judgment. This requirement is more difficult to specify and much more difficult to secure. Apart from inborn capacity, it seems to depend on familiarity with the material of the art, otherwise experience, and on a broad and sound general culture which, while including a proper awareness of science, is by no means limited to it. The ancient and honourable art of medicine is being increasingly and inevitably pressed on by applied science, and suffers as well from misunderstanding and loss of prestige. It remains, however, the backbone of medical practice and indispensable

to mankind. There is therefore an especial need to-day that its characteristic mode of activity should be understood, and should not be confused with those of the other elements that make up the complex of medicine.

MEDICINE AS APPLIED SCIENCE

The conversion of the practical arts into applied sciences is a characteristic and familiar process in modern civilisation. The rate at which this change is going on is often the subject of enthusiastic and even excited comment. To the sober realist, however, it is clear that the rule of science in medicine is still not much more than strictly local and much qualified. The cases are very few in which general principles can be applied to the individual instance with the direct precision of an engineer designing a dynamo. The diagnosis and treatment of errors of refraction, certain cases of bacteriological and of chemical diagnosis, and others of physical diagnosis and treatment, with the dietetic deficiencies, make up the examples of nearly pure applied science. Elsewhere methods of precision must be very strictly subject to the art of medicine if they are not to become a mere snare. The affectation of scientific exactitude in circumstances where it has no meaning is perhaps the fallacy of method to which medicine is now most exposed. When we observe how fully the quack has assimilated the language of science it is easy to see the need for exact definitions lest we ourselves fall, with the worthiest intentions, into something not much better.

MEDICINE AS AN EXPERIMENTAL SCIENCE

When we turn to contemplate the element of experimental science in medicine, we find that the need for some effort of definition is not less than it is elsewhere. Experimental medicine, or, as it has been more conveniently named, clinical science, is at a stage when the clear recognition of it as an independent form of scientific activity—if such it really is—is peculiarly important. If it is a science capable of being pursued and developed as such, it is a competitor for support on equal terms with the other sciences, and occupies a field particularly likely to attract endowment.

Now it is often supposed that the case for the independence of clinical science is met by pointing out that the scientific element in medicine is merely applied physiology and applied pathology. From this not very recondite truth it is concluded that any further benefit to medicine from physiological and pathological discovery can come only from work done by professed physiologists and pathologists. This view seems to ignore the way in which the sciences are distributed and have come into being. Independent sciences have arisen in the past, not apparently according to whether people said they must or they must not, but through finding a natural field and doing good work in it. According to their fields of work the sciences can be divided in a broad and simplified way into two groups. There are what we may call the *general sciences*, such as physics and chemistry, by which phenomena of a certain *kind* are chosen for study. Then there are the sciences we may call *topical*, by which phenomena of a certain *distribution* are chosen for study. Belonging to the second group are such sciences as astronomy, meteorology, and geology. The fact that they could all be described as applied physics and chemistry does not in the least impair their continued independence. These sciences have readily assimilated new discoveries in physics and chemistry that were

relevant to their work. They have, however, not been content merely to wait on progress in these sciences, but have been ready to undertake physical and chemical researches on their own account in problems presented by their material, and often with the happiest results. It is certain that meteorology and geology would not be in their present healthy state if they had not been prepared boldly to invade the realm of the physicist or chemist when occasion arose.

The analogy between the position of these disciplines and that of clinical science is close and instructive. Clinical science takes as its field the study of sick people, thus choosing a range of phenomena forming a natural group of the highest importance and interest, and no more arbitrary from the theoretical point of view than are those chosen by the meteorologist and geologist. The chief sciences that are general in the sense we have defined in regard to clinical science are physiology and pathology. While taking full advantages of any appropriate discovery in these sciences, it need no more wait on the advance of them than geology has waited on the advance of physics and chemistry, but is bound to undertake physiological and pathological researches of its own when they become relevant to its purpose. The art of medicine will long remain the chief implement of the practical doctor. Admirably adapted as it is for the conservation of knowledge it is in its very nature ill-suited for the discovery of new truth. I venture, in conclusion, to recall a classical example of this fact and its consequences.

A CLASSICAL EXAMPLE

In 1745 James Lind described the cure of scurvy by lemon juice; and in 1840 Steinhäuser, that of rickets by cod-liver oil. If these doctrines had been enunciated by teachers of great prestige they might have become accepted clinical precepts, and slowly acquired empirical stability. They did not have that good fortune. In spite of the desperate urgency of the problem of scurvy in the eighteenth century, and that of rickets in the nineteenth, no proof or disproof was established, because it is not in the nature of a practical art to seek for certainty in the scientific sense. The truth remained undistinguished among the innumerable opinions current about these diseases for 150 years in one case and 80 years in the other. As late as the admirable *Encyclopædia Britannica* of 1911, the most authoritative opinion inclined to ascribe rickets to an intestinal toxin and scurvy to an unknown microbe. The practical art of medicine alone knew the urgency of the problems, and actually for many years possessed the key to both. It was therefore in an extraordinarily favourable position for a direct attack on them. The method alone, it, as an art, did not and could not possess. That belonged to physiology, which for long years had no interest in the problems, and approached them at last as it were indirectly and almost with reluctance. When the cause of scurvy was at last scientifically ascertained in the classical experiments of Holst and Fröhlich two circumstances of the discovery attract our notice. It was made 173 years after Bachstrom had categorically and correctly announced the cause of scurvy and 162 years after Lind had described its cure, and it was made in the course of a research primarily undertaken for another purpose. It is difficult not to believe that an active clinical science, by its situation so favourably placed for a direct attack, could have saved some of these long and costly years.

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

THE 103rd annual meeting of the British Medical Association began in Melbourne on Sept. 9th with a civic reception at the Town Hall where the visitors were welcomed by the Lord Mayor, by Senator Sir George Pearce on behalf of the Commonwealth Government, and by Dr. Harris, Minister for Health, on behalf of the Government of Victoria. In the course of his reply, the president of the Association, Dr. S. Watson Smith, likened the rise of the city of Melbourne, which was 100 years old, to that of the B.M.A. which was only a little older. On the same evening there was a brilliant gathering at a reception given by the Government of Victoria at the National Gallery, the spacious rooms and beautiful corridors of which formed a good setting for the vivid pageant of academic robes. The Premier, Mr. Dunstan, and Mrs. Dunstan received the 2500 guests; standing with the Premier were the president-elect of the Association, Sir James Barrett, and Lady Barrett.

On Sept. 10th the adjourned annual general meeting opened in the Town Hall, in the presence of the Governor-General and Lady Isaacs, and the Governor and Lady Huntingfield, with an attendance of nearly 2000. After the induction of the new president, Sir James Barrett, his first action was to send a message of loyal greeting to the King. Sir Isaac Isaacs, in declaring the meeting formally open, spoke of the beneficent effects of medical research, and said that there was every reason to be optimistic with regard to the major problems still unsolved. The Lord Mayor of Melbourne then presented the flag of the city to the Association, and Sir James Barrett later delivered the presidential address on hospital problems which was summarised in a leading article in our issue of Sept. 21st. Before the meeting closed, a telegram was received from the King conveying thanks for the president's message.

On the afternoon of the 10th services were held at St. Paul's Cathedral, where the sermon was delivered by the Bishop of Wangaratta, and at St. Patrick's Cathedral. The president's reception took place in the Town Hall that evening, when over 3000 guests were present.

ACADEMIC HONOURS

On Sept. 11th, at a special ceremony in Wilson Hall, Sir James Barrett as Chancellor of Melbourne University welcomed the visitors, and conferred honorary degrees as follows:—

Doctor of Medicine.—Lord Horder, Sir Henry Gauvain, Dr. J. S. Fairbairn, Dr. Robert Hutchison, Prof. Edwin Bramwell, Sir William Willcox, Sir Lindo Ferguson (Dunedin), Sir Ewen Maclean, and Dr. E. Kaye le Fleming.

Doctor of Dental Science.—Dr. E. W. Fish.

In acknowledging the honour on behalf of his fellow graduates Dr. Hutchison said that medicine should keep in the closest touch with the universities so that the academic spirit might permeate its teaching and practice. Reform of the medical curriculum was desirable, and he considered that what was needed most was some change in the student's pre-medical education. At present skilled technicians rather than educated men were being "turned out," with the result that medical literature, though it abounded in facts and details, was comparatively poor in ideas and generalisations, while

in point of expression and style it compared unfavourably with the medical writings of last century. Dr. Hutchison then described the development and present state of his own specialty, pædiatrics, and made a plea for a more generous academic recognition of this subject. In England and Australia such recognition was sadly lacking: there were only two chairs in the subject in England and two in Scotland. Unlike many other specialties, pædiatrics was not a narrow restricted subject, but was as broad as medicine itself, and worthy to rank with the great triad of medicine, surgery, obstetrics and gynæcology. One way in which its importance could be immediately recognised by universities was to give it more prominence in the 'final examination.

Another impressive ceremony followed, in the admittance of 16 Australasian doctors to membership of the British College of Obstetricians and Gynaecologists. For this purpose Sir James Barrett vacated the chair in favour of Dr. Fairbairn, president of the College.

LECTURES

Next day, at a meeting of the Royal Australasian College of Surgeons, Mr. R. B. Wade, the president, bestowed honorary fellowships on Prof. E. W. Hey Groves and Mr. H. S. Souttar; and Prof. Hey Groves delivered the first Hamilton Russell memorial oration, entitled the Romance of Surgery. He began by describing the life and work of Hamilton Russell, who died in Melbourne in 1933, and spoke of the innate modesty which forbade him to take pride in anything but the fact that he was a pupil and last house surgeon of Lister. In the course of his lecture Prof. Hey Groves also had something to say on hospital policy, and maintained that the time had come when every hospital which undertook the treatment of the sick and the investigation of disease must come under public control—for example, that of the Ministry of Health. It should be no longer possible for a private person to give or bequeath a hospital to the community without inquiry by the Ministry of Health as to how that hospital was to be supported, whether it was needed, and above all how it was to be staffed. Now that the hospital represented a scientific clinical laboratory in which the work must be highly differentiated and specialised, it was obvious that multiple small hospitals with no connexion with one another and no responsibility except to their own directors were an absurdity.

Other lectures were given during the week by Sir William Willcox (dental sepsis and its relation to focal infection), Sir Ewen Maclean (the general practitioner and forceps), Dr. S. Watson Smith (skin manifestations in diagnosis), Prof. Edwin Bramwell (specialism: neurology and medicine), Mr. H. S. Souttar (oesophageal obstruction), Dr. Robert Hutchison (dyspepsias of childhood), and Prof. Hey Groves (the "valley of dry bones").

Lord Horder gave a "popular lecture" on eugenics, Dr. H. Guy Dain an address on National Health Insurance, and Dr. Z. Mennell the Embley memorial lecture.

EXHIBITIONS AND EXHIBITS

A doctors' hobbies exhibition, organised by Dr. H. C. Colville and housed in the geology school at the University, attracted much attention. It included examples of the beautiful work of Dr. Julian Smith and many other amateur photographers, especially noteworthy being the contributions of Dr. Harold Moore and Dr. C. H. Kellaway's photographs of

Australian birds at the nest. Dr. Colville's portraits, Dr. C. T. Stephen's water-colour studies, and Dr. Douglas Thomas's landscapes were of particular interest, while Dr. Stephens also had carvings in stone and wood. Dr. G. Kaye showed a home-made lathe and a large collection of beautifully finished chrome-plated surgical instruments which he has made, including even bronchoscopes, cesophagoscopes, and illuminating laryngoscopes. Dr. D. G. Renton exhibited home-made anæsthetic apparatus, and Dr. Ivan Connor furniture of excellent workmanship. Collections of stamps, coins, old books and documents, pewter, spoons, pottery and porcelain, antique silver, native weapons, and various kinds of needlework, completed a display of very diverse talent.

A museum, prepared for the occasion by a committee of which Prof. F. Wood Jones, F.R.S., was chairman and Dr. E. S. J. King hon. secretary, was housed in the University anatomyschool. No complete account can here be given of the magnificent collection brought together, but a few of the exhibits may be singled out for mention.

Dr. F. M. Burnet demonstrated lesions produced by viruses growing on the chorio-allantoic membrane of the developing hen's egg—a cultural method likely to be valuable because it provides means of measuring quantitatively the concentration of certain viruses. Exhibits of Australian snakes and the properties of their venoms were given by the Hall Research Institute and the Commonwealth Serum Laboratories. Specimens and photographs of *Tania saginata* and of its production of "beef measles" in the ox, exhibited by Dr. Penfold and Miss Phillips of the Baker Research Institute, depicted with unusual completeness and clarity the life history of this parasite. Dr. R. A. Willis provided photographs and maps illustrating the structure of teratomata. The University department of bacteriology displayed a variety of exhibits, and a fine collection of specimens of eye diseases from the Alfred Hospital and the Eye and Ear Hospital was exhibited by Dr. J. R. Anderson and Dr. R. B. Maynard. Dr. R. Webster of the Children's Hospital showed a large series of specimens illustrating almost the whole of the pathology of childhood. The cranial characters and outstanding racial features of Australian and Tasmanian aborigines were illustrated by specimens exhibited by Prof. F. Wood Jones. From the Hall Research Institute and the University pathology department came exhibits illustrating pulmonary pathology (Dr. E. L. Cooper) and hydatid disease (Dr. R. J. Wright Smith). From the Baker Research Institute, Alfred Hospital, and University pathology department came a collection of intracranial tumours, displayed by Dr. L. B. Cox. Specimens illustrating diseases of bone was arranged by Dr. R. D. Wright, of the University pathology department; from which also came specimens of diseases of the thyroid gland, of the pancreas, and of the heart and arteries (arranged by Dr. M. C. Davis). Dr. E. S. J. King showed exhibits of the Golgi apparatus in various normal and diseased tissues. Several collections of skiagrams covered a large part of the field of radiography. Prof. R. Marshall Allan had collected from the various hospitals an almost complete series of gynaecological and obstetrical abnormalities.

Each member of the meeting received a copy of the Book of Melbourne, compiled by a committee consisting of Drs. A. P. Derham, E. Ford, T. Blois Lawton, and W. G. D. Upjohn, and edited by Dr. Mervyn Archdall, which is full of interesting information well presented. The subjects dealt with include the growth and development of the State and city, the history of the medical school, the organisation of medical research and practice in Australia, the Victorian hospital system, public health in Victoria, education in Victoria, the Australian aborigines, Australian animal and plant life, art in Australia, and sport.

SECTIONS OF MEDICINE AND SURGERY

At a combined meeting of these sections, presided over by Sir HENRY NEWLAND (Adelaide), Lord Horder and Sir Thomas Dunhill (London) opened a discussion on

Thyrotoxicosis

LORD HORDER said that thyrotoxicosis was an unsatisfactory name, because there was no proof that the syndrome was primarily due to either hyper- or dysfunction of the thyroid gland. Although the disease had toxæmic features, the precise source and nature of the toxæmia were obscure and the pathogenesis of the disease unknown. The thyroid might be more sinned against than sinning. Efforts at analysis of the syndrome had perhaps confused rather than clarified our ideas. As to ætiology, there was a diathesis of Graves's disease, sex and sex epochs were of obvious importance, and so was psychic trauma. Some workers laid stress on focal sepsis, but the speaker found the search for this disappointing in most cases. In the established disease endocrine imbalance became obvious, and the symptoms unmistakable. It was in the early less obvious cases that diagnosis was most important. Training in observation of facies and behaviour was the key to the detection of early cases. If, instead of hurriedly falling on the patient with all our diagnostic equipment, we were merely to "stand and stare," it would be more often evident to us that the patient was staring. Minor symptoms—rapidity of manner, the moist hand, flushing, emotional and temperamental changes, and so on—were to be watched for. In treatment, judicious but uncompromising ordering of the patient's routine of life was essential; and bromides or belladonna were helpful in some cases. The so-called specific sera were valueless. Partial thyroidectomy had so completely justified itself that discussion of this subject was superfluous. There were three main indications for surgical treatment: (1) persistence of symptoms after six months' proper control of the patient's routine life, (2) definite relapse after stabilisation on a satisfactory routine, and (3) the appearance of auricular fibrillation or cardiac dilatation. Thyroidectomy achieved its best results in well established cases. When we knew more of the nature of the benefits of thyroidectomy, the pathogenesis of the disease would be better understood.

SIR THOMAS DUNHILL said that in spite of improvements of surgical treatment, the Registrar-General's figures showed a great increase in the numbers of deaths from Graves's disease in Great Britain in recent years. Exaggerated statements were often made about this disease, such as that rest and iodine would always make operation safe, or that surgery guaranteed a cure. These were mis-statements, and the word "cure" had much better be dropped. As to symptomatology, the patient's inherited constitution was probably of main importance in determining to what organ or function the principal symptoms would be referable. With regard to cardiac failure, fewer well-logged cases were seen than formerly and more with auricular fibrillation. Most of the fibrillating cases regained normal rhythm after operation, but careful control of régime thereafter was essential if relapses months or years later were to be avoided. Glycosuria was often the main symptom, and operation was often efficacious in removing this. The most pathetic group of cases comprised those with change of temperament; and, before operating on these, careful consideration must be given to past and family history, and consultation

with an experienced physician was essential. A decided risk was the development of a demented state following operation. The worst patients to handle were those who were badly emaciated; it was often essential to operate on these in stages, and ligation of the thyroid arteries was helpful in improving nutrition. In assessing operative mortality, it must be remembered that patients with Graves's disease not infrequently died suddenly quite apart from operation. Sir Thomas Dunhill then described—as an unusual symptom—the development of bilateral patches of mucinous degeneration beneath the skin of the legs, associated with coarseness of the skin itself. These patches, which had been badly named "localised myxœdema," disappeared along with the exophthalmos after successful operation; and it was pertinent to ask whether a similar lesion of the orbital tissues was responsible for the exophthalmos. With regard to the operation in severe cases, the smallest possible inroad was desirable. The statement often made that excision removed the source of the poison and that once over the operation the patient would thereafter steadily improve was false. There was little doubt that storage of the secretion in tissues other than the thyroid could persist for days or weeks.

DISCUSSION

Prof. C. E. HERCUS (New Zealand) said that in New Zealand both simple goitre and exophthalmic goitre were very common, and the two conditions were clearly related. The incidence of thyrotoxicosis was highest in endemic goitrous districts. From the data collected by the thyroid clinic in Dunedin, it appeared probable that there was no real basis for the distinction between primary Graves's disease, secondary Graves's disease, and simple goitre. The cases of simple goitre often exhibited mild symptoms of thyrotoxicosis. New Zealand provided many examples of familial thyrotoxicosis.

Dr. A. W. HOLMES A COURT (Sydney) briefly outlined some aspects of diagnosis and medical treatment. He considered that irradiation with X rays was useful in relatively few cases, those with early diffuse enlargement. Iodine amelioration was well recognised but by no means invariable. He mentioned a case in which cardiac failure had ensued despite very drastic attack on "septic foci."

Sir CARRICK ROBERTSON (New Zealand) endorsed the remarks of Prof. Hercus regarding the incidence and relationships of various types of goitre in New Zealand. He deprecated the indiscriminate and long continued use of iodine. He performed his operations in one stage wherever possible, removing about four-fifths of each lobe. Among 754 cases he had had occasion to do the two-stage operation in only two. Ligation of the arteries was a valuable aid. He used local pericaine anaesthesia with proper premedication, and adjuvant gas and oxygen. If cyanosis appeared during operation, he did not hesitate to open the trachea which he sutured again when the operation was completed. He had had seven deaths, a mortality of about 1 per cent. Four of these were in cases of "apathetic" thyrotoxicosis with cold, dry skin, cases which he therefore regarded as bad surgical risks.

Dr. H. HUME TURNBULL (Melbourne) said that while it was true that even severe cases did sometimes recover without special treatment, surgery was the only really valuable method of treatment. Although he himself was a physician, he thought that the physician played a relatively slight part in the treatment of thyrotoxicosis. Sir Thomas Dunhill

had remarked on the increasing number of deaths from Graves's disease recorded by the Registrar-General; but this might easily be complementary to his other observation that water-logged cardiac cases were diminishing; cases which formerly were classified as dying from "heart failure" now being correctly diagnosed as due to thyrotoxicosis. As to focal sepsis, while there was no doubt that this aggravated the disease, he had never seen a case in which thyroidectomy had been avoided by removal of septic foci. The trend of the present discussion had been to emphasise the danger of operation; but he thought that greater danger lay in non-operative treatment, and surgeons should not be too modest.

Dr. ALAN NEWTON (Melbourne) agreed with Dr. Turnbull that the increasing recognition of the thyroid origin of heart failure explained the increasing number of deaths recorded from thyrotoxic disease. Dr. Newton referred to the serious complications of exophthalmos; and to an unusual manifestation of Graves's disease, paresis of the muscles of the upper parts of the face. The surgeon should remember that these patients were frightened people, and therefore pre-operative treatment should be by the surgeon himself and the patient's nurses should not be changed. It was difficult to obtain these conditions in public hospitals, and this might account for the higher mortality-rate in these institutions. In his own private practice the mortality-rate was 0.4 per cent., but at the Melbourne Hospital his cases had a mortality of 3 per cent. Analysis showed that nothing short of subtotal thyroidectomy gave satisfactory results.

Dr. S. PERX (Melbourne) upheld the view that focal sepsis was an important causative factor.—Dr. S. V. SEWELL (Melbourne) endorsed the remarks of Dr. Turnbull on the preponderating value of surgical treatment.—Dr. C. DENNIS (Melbourne) said that over-treatment with X rays had brought this mode of therapy into disfavour, and asked the openers whether they had seen benefit from repeated moderate doses.

Dr. H. POATE (Sydney) said there were three main clinical types of the disease, the cardiac, the nervous, and the metabolic. X ray treatment was of value in young patients with cardiac symptoms, but not in any other cases. He endorsed Sir Carrick Robertson's remarks on the risks of "iodine addiction." He believed that the thyrotoxic patient was on the verge of acidosis, and that pre- and post-operative alkalisation was of decided value.—Prof. A. M. DRENNAN (Edinburgh) recalled the importance of iodine deficiency in the causation of goitre, and commented on the low iodine content of the hyperplastic thyroid tissue in thyrotoxicosis.—Dr. F. HANSMAN (Sydney) said that in thyrotoxicosis there was loss of calcium and phosphorus from the body and this suggested the operation of some endocrine factor other than thyroxine.

Lord HORDER, in reply, said he wished the problem was as simple as some of the speakers' remarks implied. He again stressed the fallacy of assuming that Graves's disease was initially one of thyroid disfunction. Because thyroidectomy at a certain stage of the disease achieved such beneficial results, it was fallacious to argue that the thyroid was the primary source of trouble. The position was analogous to that of splenic anaemia or of acholuric jaundice, in which the beneficial effect of splenectomy at a certain stage did not necessarily mean that these conditions were primary diseases of the spleen. Lord Horder regretted that Prof. Hercus had omitted to

describe the nature of the mild supposedly toxic symptoms in patients with simple goitre in New Zealand: it was important not to mistake the symptoms of simple nervousness for toxic symptoms. He disagreed with Dr. Turnbull's view that the physician was almost useless in treating Graves's disease; the physician should play an important part in close collaboration with the surgeon. A final warning with regard to operation was—if you wish to do a disservice to thyroidectomy, do it too early.

Sir THOMAS DUNHILL, in reply, urged Prof. Hercus to publish details of his observations on the relationship which he had described as existing between simple and toxic goitre in New Zealand. Regarding Sir Carrick Robertson's technique, Sir Thomas said it was also his own practice to complete the operation in one stage whenever possible; but there were cases which could only be dealt with safely in two stages. In reply to Dr. Dennis, he maintained that X ray treatment was of value in early cases in young people; but there were many cases which, after alleged cure by X radiation, returned with auricular fibrillation. In treating Graves's disease there was need of the closest coöperation between physician and surgeon; and we must retain sanity, moderation, and judgment.

SECTION OF OBSTETRICS AND GYNÆCOLOGY

At the first meeting of this section, held under the presidency of Dr. J. S. FAIRBAIRN (London), a discussion on the present position of

Cæsarean Section in Obstetric Practice

was opened by Mr. J. BRIGHT BANISTER (London). At first, he said, this operation was adopted as a life-saving method for both mother and child, but there was now a tendency to adopt it as the easiest method of delivery. Such interference on insufficient indication was more readily undertaken by those who did not appreciate the risks involved. There was no doubt that the use of Cæsarean section was excessive, with an associated increase in the maternal death-rate, and a reduction was strongly to be recommended. The operation occupied an unjustifiable position in obstetric practice, its incidence being too high, its indications too wide, and its mortality too great for any method attempting to lessen maternal mortality. Analysis of a series of cases reported in the *American Journal of Obstetrics* for September, 1928, showed that these strictures were not undeserved; for in this series 55 separate indications for Cæsarean section were noted, including such conditions as failure to progress, advanced age of mother, breech presentation, previous perineal repair, and unwillingness to undergo pains of labour. The maternal mortality-rate in the series was 6.6 per cent.; could it therefore be defended on the grounds of safety? In England and Wales the maternal mortality for Cæsarean section cases was 16 times as great as that for obstetric cases generally. In British maternity hospitals the mortality-rate of Cæsarean section undertaken by competent operators was 5.8 per cent. Mr. Banister considered that a purely surgical outlook on purely obstetric problems was a patent cause of the great increase in the operation. A contempt for Nature came with the knowledge that the uterus can be easily emptied. "Trial labour" was often a travesty in contracted pelvis. Before Cæsarean section was undertaken a trial labour patient should have had second-stage pains for several hours. There was also failure to appreciate

the conditions present in a given case; "failure to progress" meant that the obstetrician was ignorant of the conditions present. It was essential that obstetrics should be in the hands of obstetricians and not of surgeons who did obstetrics. He considered that unnecessary value was given to the life of the child to the sacrifice of the life of the mother. He had been surprised by the importance laid on laboratory findings as compared with clinical investigations in American obstetric practice. For example, the Cæsarean rate in one hospital was 4.2 per cent.—for such indications as "slight blood pressure," or "slight rise in blood-urea." It was not sufficiently realised that Cæsarean section was an abdominal section which had at least a 1 per cent. operative mortality compared with a 0.2 per cent. obstetric maternal mortality in all cases. Cæsarean section at present was a prostitution of a useful operation which was performed far too freely when accurate obstetric methods would avail.

Prof. J. B. DAWSON (Dunedin, New Zealand) spoke of the difference between British and American obstetric figures. Normal labour was a perfect mechanical procedure, whereas difficult labour was very imperfect. He suggested that the comparison of statistical figures is unfair, in that the mortality of a serious group of cases is compared with the mortality of all cases, 90 per cent. of which are normal. What we wanted to know is what would have happened if the obstetric dilemma had been circumvented by methods other than Cæsarean section. He believed that the procedures of high forceps or craniotomy would have the same mortality. He considered that mortality received too much consideration as compared with morbidity; many women had vaginal deliveries at great maternal cost and a staggering number of foetal deaths. To finish vaginal delivery might be a personal triumph for the obstetrician, but was often disastrous for the mother. Thirty years ago Cæsarean section was said to be performed too often; the mortality was still too high and Prof. Dawson believed that this was due to too many operations performed too late. The operation was not used too much but was too much delayed. Improvement would come by reducing delay rather than reducing use; great care should be taken to select the optimum time of performance and suitable surroundings. The training of an expert surgical team was an important factor in the success of this operation.

Dr. W. IVON HAYES (Melbourne) agreed that bad selection of cases, delay, and faulty technique were responsible for the present high maternal mortality. The high death-rate associated with cases of renal toxæmia called for the greatest conservatism and the temptation to operation must be resisted. Severe accidental hæmorrhage had not been treated by Cæsarean section for the past six years in the Women's Hospital, conservative measures having proved satisfactory. In the management of disproportion one was faced with elective Cæsarean section or trial of labour. The fatalities occurred in the late cases, and the mortality rose very rapidly after membranes had been ruptured for more than 12 hours. Lower uterine section should be used in all potentially septic cases, while Cæsarean hysterectomy should be undertaken for definite septic conditions. He agreed that Cæsarean section was an easy escape from difficulties but a dangerous method of delivery, and the results could be improved by earlier recognition of indications.

Dr. H. A. RIDLER (Sydney) said that generally the

less competent the obstetrician the more Cæsarean sections he performed. The great widening of indication in the last 20 years might be evidence of the craze for speed. The high mortality-rate was lessened by adopting the lower-segment operation after "failed forceps" or prolonged labour with ruptured membranes. Late recourse to operation, unfortunate choice of case, and unsuitable surroundings all gravely increased the maternal mortality-rate. He concluded with the plea for more intensive obstetric training.

Dr. M. ELLIOTT SMITH (Brisbane) presented a series of figures from the Queensland Obstetrical Society. Antenatal care was still, he said, the most important factor and good surroundings for delivery were necessary if difficulty was anticipated. Cæsarean section had no place as an operation of last resort; but it was sometimes hard to decide when it should be performed.

Dr. F. BROWN CRAIG (Sydney) pointed out that Cæsarean section was done more often in the suburbs than in the teaching hospitals. He considered that mature obstetric opinion should always be obtained before the operation is undertaken.

Dr. E. R. WHITE (Melbourne) held that often the operation offers the best chance of a living child to the elderly primipara. The after-care of Cæsarean section was important; one of the most serious complications being abdominal ileus, the incidence of which was much reduced by adequate pre-operative care.

Dr. J. S. GREEN (Melbourne) said that the greatest problem was the nearly normal case which had a tedious labour. There was great risk of stillbirth in these cases and the problem of Cæsarean section was often canvassed. He also mentioned the great difference in the incidence of the operation at various institutions. He inquired if Mr. Banister could furnish any reason for this difference in incidence. He asked also what was Mr. Banister's attitude when confronted with the choice between undertaking a difficult forceps extraction with considerable risk to the child, or performing Cæsarean section. Often there was considerable psychological difficulty with regard to the survival of the child in trial labour.

Dr. GEORGE SIMPSON (Melbourne) considered that Cæsarean section and sterilisation was the procedure of choice for cases presenting medical contraindications to further pregnancy.

The PRESIDENT considered that the emphasis laid upon possible resort to Cæsarean section lessened the effect of good obstetric teaching. "Request" operations were ethically very undesirable.

Mr. BANISTER in reply said that the meeting evidently agreed that Cæsarean section was undertaken too often and that each case must be considered separately. The "quick" decision in obstetric cases was bad, leisurely methods being desirable. The quasi-normal case should be given a reasonable trial of labour. He could not agree that an elderly primigravida was a "ripe" subject for Cæsarean section. In reply to Dr. Green, he said that the East End Maternity Hospital is staffed by general practitioners, but that the vast majority of the work is done by the matron—an outstanding midwife. This hospital served the same district as the London Hospital where a large number of the abnormal cases were admitted. There was, therefore, not quite the same influx of all types of cases at the East End Hospital. In making a decision in a difficult case, one should make a careful examination under general

anæsthesia and then decide between Cæsarean section and the application of high forceps.

Placenta Prævia

Sir COMYNS BERKELEY (London) in opening a discussion on this subject based his remarks on an exhaustive investigation of 4374 cases collected from 19 British hospitals. He advanced a plea for the universal adoption of the report-form approved by the obstetrical section of the Royal Society of Medicine. As a result of his investigation, Sir Comyns was enabled to formulate a series of rules to be observed in the treatment of placenta prævia. These were, briefly: (1) to control the bleeding as soon as possible; (2) to combat shock, if present; (3) to use every endeavour to prevent sepsis; (4) not to hasten delivery, apart from cases of Cæsarean section; (5) to make no pelvic examination unless prepared to commence treatment at once; (6) not to expel the placenta until entirely separated, unless there was hæmorrhage; (7) to use a pointed instrument to pierce the placenta, should this be necessary; (8) to use an efficient antiseptic solution, if packing of the vagina is undertaken; and (9) to avoid Cæsarean hysterectomy if possible. Control of the hæmorrhage should be the main aim in treatment as the patient is never safe until the uterus is empty and well retracted. Packing the vagina was deprecated in view of the increased rate of sepsis associated with it.

Shock was a frequent cause of death and should be treated early and energetically by intravenous glucose therapy or blood transfusion. The commonest cause of death, apart from those who died undelivered, was sepsis, and the greatest care in the management of these cases was essential. If shock had been treated and hæmorrhage controlled, there should be no haste in delivery, avoiding such procedures as version and immediate extraction, or the abuse of pituitrin. Pelvic examination might increase the seriousness of hæmorrhage and should only be undertaken if one was prepared to control any further blood loss at once. No attempt should be made to expel the placenta until it is completely separated unless post-partum hæmorrhage occurs, even though it is small in amount, when the uterus must be emptied. If the placenta was central in position and had to be perforated, a pointed instrument such as a uterine dressing forceps should be employed because it carried less risk of further placental separation. The maternal mortality of Cæsarean hysterectomy was very high and the operation should be avoided where possible though it might be essential if hæmorrhage did not cease after delivery.

Sir Comyns drew attention to the diversity of methods in use in treating the various types of placenta prævia. He suggested that the best results would be obtained when one specific method of treatment was followed to the exclusion, whenever possible, of any other. Although it was desirable that the treatment be carried out by experts, in many cases immediate steps must be taken to control hæmorrhage.

When dealing with central placenta prævia the safest method for both mother and child was Cæsarean section when the patient was 36 weeks pregnant or over. With the exception of bringing down a leg in a breech presentation, the mortality of Cæsarean section was by far the lowest of any method. In cases less than 36 weeks pregnant, the advantage of Cæsarean section was not so great, but it offered

far better chances of securing a child which would survive. Even if the child was dead, Caesarean section was still the treatment of election in patients 36 weeks pregnant and over. Under 36 weeks of pregnancy the patient should be delivered by bringing down a leg. Lastly, one was justified in performing Caesarean section in a multipara over 36 weeks pregnant because the chances of a living child being obtained were good; but the operation was not justifiable under 36 weeks pregnancy, because the patient already had children, the viability of the child was much reduced, and the method of bringing down a leg in a breech presentation had a lower maternal mortality.

Incomplete placenta prævia was best treated by rupturing the membranes and allowing labour to proceed, a tight binder being applied. The death-rate associated with this method was far lower than by any other method. Bringing down a leg in a breech presentation was also satisfactory. In cases of this type Caesarean section and spontaneous labour had considerably higher maternal mortality. Lateral placenta prævia was as a rule over-treated. The safest course was to allow labour to progress without interference. The next safest methods were rupture of the membranes and bringing down a leg in breech presentation. Vaginal packing was to be condemned because of the grave risk of sepsis, and in many cases it was not satisfactorily performed.

Prof. J. C. WINDEYER (Sydney) expressed the hope that the obstetric hospitals of the Empire would adopt the form of report recommended by the obstetric section of the Royal Society of Medicine. The advantages of various forms of treatment could then be estimated with considerable accuracy. He had been an advocate of scalp traction for some years. This method possessed the advantage that a minimum of vaginal manipulation is required, that the forceps could be applied quickly through a very slightly dilated os uteri, and traction maintained by application of a light weight. It could be used in most of these cases and should take the place of vaginal plugging or bipolar version. In the management of the third stage of labour control of hæmorrhage was of the greatest importance. Careful observation of the fundus uteri and vaginal introitus was necessary. If persistent loss occurred, an attempt to express the placenta should be made. If unsuccessful, manual removal of the placenta and bimanual uterine compression with the exhibition of pituitrin should be performed. Steady compression as a rule avoided the necessity for uterine packing. Prof. Windeyer illustrated his remarks by showing the results of the last 100 consecutive cases under his care. He did not agree with Sir Comyns Berkeley that vaginal plugging was dangerous; with care risk of sepsis was not great.

Dr. A. M. WILSON (Melbourne) quoted a series of figures from Melbourne obstetric hospitals. Placenta prævia was a comparatively rare complication, he said, and consultant opinion should be obtained in these cases. The patient should be placed in satisfactory surroundings before active surgical treatment was undertaken. Painless causeless hæmorrhage usually indicated the presence of placenta prævia and the procedure to be adopted should be decided on at once. It was rare for such patients to die as a result of their first hæmorrhage and the most serious type was one that had had repeated hæmorrhages. Once diagnosed, termination of the pregnancy must be attempted immediately. Stimulative treatment was often successful. Dr. Wilson advised Caesarean section for the central type of placenta prævia.

These cases should be blood-typed on admission because blood transfusion was so often necessary. Vaginal packing was not advisable owing to the risk of sepsis. If used it should be only a temporary expedient.

With lateral or central placenta prævia Dr. Wilson advised rupture of the membranes and/or the application of Willett's clamp. Breech presentations usually did well if a leg was pulled down and the patient allowed to deliver herself. Bipolar version without extraction was the method of choice for a serious emergency if surgical aid was not available; there was, however, a great infantile mortality. Caesarean section was life-saving in many cases, but it was desirable that the patient should be a good surgical risk. It was an excellent operation in picked cases over 36 weeks of pregnancy. Simpler methods were however, as a rule, safer to the mother.

Dr. LANDER (England) inquired whether placenta prævia was a consequence of toxæmia or a mechanical anatomical mishap. In general practice one had to decide quickly in these cases. He found that the bipolar version sometimes increased the hæmorrhage and was technically difficult. He considered that rupturing the membranes and allowing the free flow of liquor amnii was usually sufficient. He emphasised the value of posture and fundal pressure. Dr. M. ELLIOTT SMITH (Brisbane) supported Prof. Windeyer in his advocacy of plugging, which was no doubt about its value, he said, but in an emergency use was sometimes dangerous because of the lack of asepsis. He had found a high forceps a useful instrument with which to perform a centrally situated placenta.

Dame CONSTANCE D'ARCY (Sydney) considered that Sir Comyns Berkeley for the nine principal cost she stressed. She commended Caesarean section. To finish the operation of choice in central placenta prævia, whilst Dr. Hicks version was very valuable for the emergency. She considered that in Australasia the American influence on obstetric practice preponderantly was stated. She drew attention to the advantages of this as a final anaesthesia in dealing with some difficult cases.

The PRESIDENT agreed that in many cases minor degrees of placenta prævia were over-treated. He advocated Caesarean section in cases over 36 weeks of pregnancy having complete placenta prævia.

Sir COMYNS BERKELEY in reply emphasised that his paper represented not his own experience, but that of a great number of obstetricians. It was most essential that having diagnosed that placenta prævia one should decide upon a method of treatment and carry it out. In general he would advise Caesarean section for the complete cases of rupture of the membranes for the incomplete cases, and watchful observation for cases of lateral and placenta prævia. He advised all members of the section to read his statistical table carefully, when he had no doubt that the best method of approaching such cases could be decided. He agreed with Dr. Wilson that the pregnancy should be terminated as soon as hæmorrhage occurred, but was totally opposed to vaginal plugging.

Summer Time, which commenced in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday, April 14th, will cease on Sunday next, Oct. 6th, at 3 A.M., when the clock will be put back to 2 A.M. The hour 2-3 A.M. Summer time will thus be followed by the hour 2-3 A.M. Greenwich time.

MARGATE AS A HEALTH RESORT

B.H.R.A. CONFERENCE, SEPT. 27TH-29TH

By providing an Indian summer of almost tropical intensity the climate of Margate did much to dispel the idea, if such still exists, that the Thanet coast is so bracing as only to be enjoyable for two or three months at the height of summer. Visitors to the week-end conference were given a cordial welcome from the Mayor and corporation whose hospitable reception included a concert at the Winter Gardens on the Saturday evening and a luncheon at St. George's Hotel on the Sunday.

TOWN PLANNING AT THE SEASIDE

The meetings of the conference began on the Saturday morning; the first subject for discussion being "Town Planning at the Seaside," opened by Mr. CLOUGH WILLIAMS ELLIS, F.R.I.B.A. He emphasised the need for co-ordinate planning in seaside resorts; looking at our coast line as a whole it was evident that the best planned towns were usually found to have been built under the benevolent despotism of some great landed proprietor; unrestrained individual enterprise was certain to result in disorder and ugliness. Those towns were fortunate which possessed streets and squares dating from the Regency or later eighteenth century. Victorian and Edwardian times were the dark ages of architecture and few seaside resorts have escaped the conglomeration of sordid streets and rows of villas which this period perpetrated. Recent years have seen a return of life to architecture, new forms are being discovered, and Acts of Parliament had now vested in local authorities powers which were being used to bring order into the planning of the towns and protection of the beauty spots from the uncontrolled commercialism of the speculative bungalow builder.

Mr. WESLEY DOUGILL, A.M.T.P.I., continuing the discussion, began by referring to the greatly increased population of the coast not only for holidays but for residence. This change has been due in large extent to improvements in road, rail, and air transport; but great has been the exploitation of the coast that the seaboard is being rapidly built up and seekers after unsophisticated resorts are being driven further along the coast until soon they will be chasing a will o' the wisp at Land's End. He suggested that government supervision was necessary to control this change which threatened to end in the building up of many headlands and other beauty spots on the coastline. Caravan and shack colonies should be concentrated in inconspicuous places. Good work is already being done under the Town and Country Planning Act (1932), which has enabled certain municipalities to acquire and zone as open spaces land near their boundaries. The speaker also referred to the advisability of more provision for indoor amusements at the seaside as the British climate is uncertain even in the middle of the summer, and if a longer season is required more must be done to entertain visitors when the beach is too cold.

Mr. E. G. S. ELLIOTT, A.M.T.P.I., directed attention to the importance in a town-planning scheme of the first impression made on the visitor. The railway station should be as near the sea front as possible, as the new arrival will receive a poor impression if he starts with a long taxi drive through mean and sordid streets which give no indication of their proximity to the sea. Aerodromes are becoming increasingly important and should be placed as near

the town as possible; this arrangement not only saves the traveller's time but, as the Germans have discovered, an aerodrome, particularly if surrounded by a park containing restaurants and tea gardens, proves a great attraction to visitors. It is important to note that while the Englishman's appreciation of architecture is negligible he has a passionate love of trees, flowers, parks, and gardens.

CONVALESCENCE ON THE THANET COAST

The subject for the afternoon session was opened by Sir LEONARD HILL who began by saying that, although there are weakly and infirm people who require warmth, a bracing sunny climate is the best for the majority. In the constitution of a bracing climate cooling power is one of the most important factors; this is very great on the top of a cliff on the east coast. Not only the actual temperature but the quality of the ray seems to be important; rays from a bright source such as the sun are more invigorating than those from a dull source. Owing to their relatively large body surface children lose heat quickly when exposed to cold moving air and require not only plenty of food but vigorous exercise to keep warm. Plenty of rest is also essential and when resting they must be kept warm. Swimming increases the heat production about ten times.

Mr. W. GREENWOOD SUTCLIFFE referred to the pioneer work of Lettsom in making Margate the first centre for the treatment of surgical tuberculosis. Rest and a maximum of fresh air and good food had always been the factors which Margate treatment depended on. Until recent years excessive operative treatment followed by extensive sepsis was often encountered. At Margate, extension for the correction of deformity, immobilisation, and an absolute minimum of surgical interference is the rule, and the results obtained are at least as good as those following more modern methods. As regards tuberculous cervical glands more than 90 per cent. disappear with conservative treatment, but if they have been present for more than six months their disappearance without operation is doubtful, and if caseation appears complete removal should be considered. The speaker also referred to the advantages of Margate as a place for convalescence after severe surgical operations.

Dr. H. M. RAVEN described the physical geography of Thanet; a rainfall of 27 in. combined with porous chalky soil and a high sunshine record (1700 hours) combined to give the district a healthy and bracing climate. The speaker thought the hardness of the water, due to calcareous matter, might be beneficial in promoting the calcification of tuberculous lesions. As regards the type of patient to be sent to Thanet, delicate and convalescent children did exceptionally well but caution was necessary with cardiac cases especially in winter and careful medical supervision was essential. The stimulating air of the district is particularly suitable for cases of malnutrition, and statistics from an open-air school for girls sent by the "Save the Children" Fund showed an average increase in weight of 7.68 lb. in three months. Boys, being more active, did not gain so rapidly.

Nervous children and those suffering from chorea are, said Dr. Raven, usually benefited, but certain highly excitable children are over-stimulated and must be transferred to a more relaxing climate. In convalescent homes supervised sun and air baths are of value and children improve much faster when weather conditions permit of this treatment. Sea-bathing is to be recommended with more caution, as when unregulated too long immersion is frequent and

may be deleterious. Paddling he considered to be a frequent cause of chills, especially among the children of visitors who often had their feet wet for hours at a time.

Dr. E. P. POULTON began by referring to the popular idea that, in regard to climate, bracing represents all that is good and relaxing that which is evil. In practice a relaxing climate is required in certain conditions, but owing to the unpleasant association the term sedative is preferable. The speaker considered that the British Health Resorts Association should initiate an inquiry into the climatology of the British Isles; the collection of data and its correlation at a central bureau would help to get away from such medico-popular writing as that the value of the seaside depends on the amount of oxygen (or ozone) in the atmosphere or even on the purity of the air. Sunbathing is the rational treatment for diseases depending on deficiency of sunlight, but Dr. Poulton doubts if perfectly healthy people are wise in attempting to pigment themselves—pigment being a natural protection against the harmful effect of the sun's rays. The value of the sea coast was recognised by Richard Russell (1700-71), who noticed that the fisherfolk were free from scrofulosis and that delicate children returned from the sea "bare-necked, their hair shaved, and tumours of the neck healed and the countenance healthy."

In the general discussion which followed there was some difference of opinion about the relative importance of exposure and infection in the production of the common cold. Several speakers congratulated the municipality of Margate on the progress that has been made in recent years in town planning and in the provision of sheltered places and amusements where entertainment can be found in bad weather.

IRELAND

(FROM OUR OWN CORRESPONDENT)

FEES FOR ADMINISTRATION OF ANÆSTHETICS

THERE has been much discontent throughout the country because of the reduction in the scale of fees previously sanctioned for the administration of anæsthetics in district hospitals. For many years a scale was in existence which, though by no means liberal, was accepted generally by the profession. Early last year the Department of Local Government and Public Health drafted a new scale which was issued to the local authorities with instructions that payments in excess thereof would not be sanctioned. The scale was drafted without notice to, or consultation with, the profession, and without any complaint having been made by the local authorities as to the previous scale. It made drastic reductions in the fees allowed, some of the fees being as low as 7s. 6d.! Protests, in which the local authorities were at one with the profession, were made by medical men all over the country, but the Department remained obdurate. Medical men have been slow to refuse their assistance, hoping that the Department would be willing to enter into discussion with their representatives, but so far this hope has been vain, and there are signs that their patience is wearing down. In County Clare recently, the medical officer of the Scariff district hospital reported to his board that it was impossible to obtain the services of medical men to administer anæsthetics to patients in the institution for the fees specified

by the Department. The Department in reply directed that all patients requiring operations be sent to the county hospital at Ennis, or, if they should be unfit for removal, that the surgeon of the county hospital should be summoned to perform the necessary operation. The board of health refused to adopt this unworkable and costly scheme, and proceeded to appoint an anæsthetist at an annual salary. In attempting to impose a new and inferior scale and in refusing to consider the matter with representatives of the profession, the Department has acted in a harsh and unreasonable way, and if there is a general breakdown as regards the giving of anæsthetics in district hospitals, the responsibility will rest with the Department.

THE DISPENSARY MEDICAL OFFICER'S RESIDENCE

It is a regulation of the Department of Local Government and Public Health that the dispensary medical officer should reside within his district. It is clear that for one reason or another it may not always be wise to insist on the letter of their rule, and it not infrequently happens that the best point for the residence from the point of view of the convenience of the patients is outside the geographical bounds of the district. The Department has in the main used a wise discretion in the application of the rule, and there is rarely cause for complaint. A curious position, however, is likely to arise in County Roscommon. The dispensary medical officer of the Kiltoom district resides and has resided for years in the town of Athlone, just outside his district. The Department refuses to sanction this arrangement any longer, and has directed the board of health to choose a site and build a residence within the district. To this course the ratepayers object, urging that the salary and private practice of the district would not attract an experienced doctor, and that the people of the district would thereby suffer. In this view the chairman of the board of health concurred, stating that if the doctor was compelled to live in the district and pay an economic rent for his residence, in the event of a vacancy they would find no applicants to fill it. It was stated also that in the adjoining Brideswell district there had been a succession of 72 doctors in 70 years!

HEALTH OF COUNTY DUBLIN

In his annual report for 1934 Dr. J. A. Harbison, medical officer of health for County Dublin, records a steady increase in the birth-rate and a fall in infant mortality. The general death-rate had increased slightly from 13.8 per 1000 in 1933 to 13.9 in 1934. Heart disease was by far the largest individual cause of death and accounted for one-sixth of the total number of deaths. The number of deaths from cancer had fallen from 137 to 122 in the year, and there was also a fall in the number of deaths from infectious diseases, but deaths from measles numbered 47, showing a higher total than all the deaths from acute notifiable infectious diseases together. Speaking of tuberculosis, Dr. Harbison states that there was considerable difficulty in obtaining sufficient beds for patients, particularly for chronic and advanced cases. He remarks that too many of the patients failed to present themselves for examination until the disease was far advanced. There was no appreciable reduction in the mortality from tuberculosis in the past four years. As to housing, apparently the worst housing conditions exist in the suburban areas, where there are numerous collections of badly lighted,

POST-GRADUATE LECTURES

LAST week-end several of the London teaching hospitals held short post-graduate courses, and as in previous years we propose to publish abstracts of some of the lectures delivered. Of the three which are summarised below, those of Dr. Miller and Mr. Williams were given at St. Mary's and Prof. Wright's at the Middlesex Hospital.

SLIMMING PROBLEMS IN CHILDREN AND ADOLESCENTS

(Dr. REGINALD MILLER)

By the use of the term "slimming problems" I intend to convey the fact that I do not propose to deal merely with the treatment of obesity. There is a good deal more of interest in the subject than that. Prevailing fashions have led to much that is extravagant in thought and practice in these matters, and perhaps our profession has not altogether escaped these influences. In one respect the patients whom we see on account of their supposed over-weight differ from the ordinary run of cases in that at the back of their trouble there is rarely any physical disease or disorder, and in slimming problems the psychology of the patient comes to the front. It is, perhaps, a pity that the degree of slimness at the moment demanded by fashion does mean in many instances real under-nourishment and a consequent strain on physical and nervous health. Most people may be said to have an optimum weight and this is not necessarily their minimum or maximum weight. Sometimes by remembering this we can be of help to those who consult us.

It is convenient to consider the subject in four age-groups: (1) infancy; (2) childhood to puberty; (3) puberty to adolescence; (4) adolescence.

1. *Infancy*.—Towards the end of infancy, before the child begins to walk, there is a natural fat period. Provided that rickets, anaemia, and hypothyroidism are absent, the condition is harmless though it may delay slightly the onset of walking. The condition should generally, therefore, be left alone. If for any special reason it is necessary to treat the over-weight it should be done by reducing the intake of fat and sugar rather than by cutting down the bulk of the food taken.

2. *Childhood to Puberty*.—During childhood up to the age of puberty there are many over-fat children. An attempt may be made to class them into three groups—endogenous, exogenous, and endocrine; but

(Continued from previous page)

damp, and unhealthy houses which are huddled together. Even in State-provided houses, as in labourers' cottages, there are many instances of overcrowding, a new generation having sprung up since any appreciable effort in housing has been made. So short is the supply of houses that many people are forced to occupy houses at rents far beyond their means. Dr. Harbison knows that many families are paying rents of 10s. to 15s. per week out of a total weekly income of 25s. He makes a strong case for town planning which "has a biological significance as well as a structural and economic one."

for individual cases it is none too successful. Unfortunately doctors are apt to focus upon the endocrine possibilities and commonly diagnose Fröhlich's syndrome on totally insufficient grounds. This syndrome is in reality a very rare condition and mere fatness is not enough for its diagnosis. Some degree of physical or genital infantilism should be present, and although the second is difficult to recognise before puberty (though often diagnosed), delay in ossification in bones can be sought for in order to substantiate physical infantilism. Fröhlich's syndrome is due to organic disease affecting the pituitary and supposed to cause deficient secretion of the posterior lobe. Most of the over-weight children at this age are large in stature and powerful in build as well as fat, and if there is a pituitary influence it is more likely to be an excess of anterior-lobe secretion rather than a deficiency in posterior-lobe secretion. Caution should be exercised before diagnosing Fröhlich's syndrome, as later the punctual appearance of puberty may show the diagnosis to have been wrong. Treatment at this age is rarely necessary, and the use of thyroid as a routine measure is to be deprecated.

3. *Puberty to Adolescence*.—Even after puberty is well established a few children, chiefly girls, remain over-fat during their last years at boarding-school. We hear much of the woes they are supposed to suffer from the taunts of their school-fellows, but this is quite exceptional. Usually these fat girls are very popular and are jolly, happy, and prosperous folk. The great difficulty is to get them to take the slightest interest in their weights or figures while they are at school; it is usually the parents who are anxious. Such cases will have sometimes to be dieted even while at school, and this needs to be done carefully. The girl will be probably leading a very active life and may be working for examinations, and if the diet is so restricted that she is perpetually hungry her work will suffer and she will be rendered miserable and bad-tempered. The fats and carbohydrates in the diet must be ruthlessly cut down, and the girl fed on proteins with plenty of green vegetables, salads, fruit and cheese, with bread substitutes and saxon. Such a diet, although dull, is not unpalatable. Its chief drawbacks are the absence of bread and butter, and the fact that it cannot be varied by occasional feasts. Of it the child may eat, if not *ad lib.*, at least enough to be satisfied.

4. *Adolescence*.—After leaving school the adolescent who is over-weight generally becomes interested in her appearance and if then she slims sanely all is well. Occasionally, however, the slimming process gets altogether out of hand and the girl reduces herself to a condition of physical exhaustion and nervous prostration. Such cases are all very much alike, the patient swearing that she feels well and that she is better and happier on the restricted diet; but her cold extremities, her slow pulse, her excessive emotionalism and bad temper belie her words. Although she starts on the process of slimming voluntarily it seems to develop into an hysterical obsession, and the ultimate state of the patient may give rise to real anxiety. In the treatment of such cases it is important that sooner or later the girl should be made to face up to the reality of her condition and the unwisdom of such underfeeding, for she is not cured in any real sense until she takes a natural amount of food for natural reasons.

RECENT WORK ON VISCERAL SENSIBILITY

(PROF. SAMSON WRIGHT)

I HAVE selected the subject of visceral sensibility to talk about because it deeply interests both myself as a physiologist and you as clinicians; it is not an easy problem for either of us to study because experiments on animals suffer from obvious limitations, and observations made in the course of disease are often difficult to interpret. Experience has shown that individual organs must be investigated separately as there are few conclusions that apply equally to them all. I believe that a good deal of the present confusion is due to the hasty attempts which have been made to argue by analogy from one viscus to another.

You are all familiar with Mackenzie's studies on the heart. He showed that certain disorders of the myocardium are associated with no local or visceral pain, but give rise to referred pain in the distribution of certain posterior nerve-roots. As far as we know the cardiac pain-afferents enter the upper thoracic posterior nerve-roots only, but it is well recognised that the pain may be much more widely distributed and be felt in the neck or jaws or abdomen. I have suggested that this phenomenon be called "sensory irradiation," and there is some evidence that the extent of the irradiation may be related to the severity of the heart lesion. The pain-afferents are thought to produce some obscure change in the spinal cord to set up a so-called "irritable focus" which modifies the character of the impulses entering from the skin and muscles in the disturbed segments and so produces tenderness. Lastly, reflex motor effects like intense muscular contraction (thoracic constriction) or salivation may occur. The work of Lewis on the production of pain in an ischaemic-exercised limb seems to prove that muscular activity liberates an agent—the so-called P-factor—which can stimulate sensory nerve-endings and arouse pain. He believes that under normal conditions of the circulation the P-factor is removed as rapidly as it is formed, and never accumulates to threshold concentration; but if the circulation is inadequate it is retained in the tissues and pain results. When a tissue breaks down as a result of infarction the same factor is probably produced. It seems pretty certain now that typical cardiac pain is always produced by ischaemia either absolute or relative—that is by coronary thrombosis or by a coronary flow which is inadequate for the current needs of the heart—and that Lewis's chemical factor is the stimulating agent at work.

I would now like to draw your attention to some very convincing and illuminating experiments which have been carried out in recent years by Capps in America and which I think have greatly increased our knowledge of the sensibility of the serous membranes—the pleura, pericardium, and peritoneum. His pleural studies have been carried out as follows: In cases of pleural effusion he pushes a hollow trocar through the chest wall into the pleural cavity; before much fluid escapes a long stiff silver wire is passed through the cannula and brought into contact with various aspects of the pleural membrane. He found that the *visceral* pleura which lines the lung is entirely devoid of pain sense. Pressure on the *parietal* pleura, however, gives rise to a sharp pain which is located with considerable accuracy over or near the site of stimulation. The sensory nerves involved are of course the intercostals which richly supply this region of the pleura. His most interesting observations were made on the *diaphragmatic* pleura. As

you know, the central part of the diaphragm is supplied by the phrenic and the afferents from this region enter mainly the third and fourth cervical posterior nerve-roots; the peripheral part of the diaphragm is supplied by the lower intercostals and the afferents pass into the seventh to the twelfth thoracic posterior nerve-roots. Stimulation of the diaphragm never produces local pain; it is always referred. From the central diaphragm the pain is referred to the neck and the upper part of the shoulder; from the peripheral diaphragm to the lower thorax, the lumbar region, or abdomen. The stronger the degree of pleural stimulation the more widespread is the distribution of the referred pain, and it may sometimes extend to the *other* side of the body too. Furthermore, the pain is associated with *tenderness* and *muscular rigidity*. I think you will agree that this work on the diaphragmatic pleura forms a most convincing demonstration of the general truth of Mackenzie's notions.

In the case of the pericardium, however, the findings are rather different. The lower part of the fibrous pericardium is supplied by the phrenic and gives rise to referred neck pain, but the inner surfaces of the pericardial sac are seemingly painless. Capps suggests that when severe pain accompanies pericarditis it is due to one of three things—involvement of the mediastinal tissues or of the diaphragmatic pleura or interference with the coronary flow.

The findings in the case of the peritoneum are identical with those with the pleura. The visceral peritoneum is insensitive; the parietal peritoneum gives *localised* pain associated with tenderness and muscular rigidity; the diaphragmatic peritoneum gives rise to referred pain in the neck or lower part of the body wall.

You must remember, however, that the hollow viscera are not insensitive to all stimuli. Pain can be set up by pressure changes which may result either from excessive distension or violent contraction of the muscle wall. There is still much dispute whether the pain is felt vaguely in the affected viscus or is referred to the surface of the body; most people, contrary to Mackenzie, hold the former view. The evidence suggests that so long as the disorder is limited to the viscus or to its visceral peritoneum there is *no tenderness or rigidity*. These latter symptoms only develop when the parietal peritoneum is affected. This matter I believe still requires much investigation and its practical importance is obvious; it is eminently a problem which you are fitted for and have the opportunities to clarify.

HORMONE THERAPY IN GYNÆCOLOGY

(MR. LESLIE WILLIAMS)

THE hormones of most practical value in gynaecology are oestrin, progestin, and prolactin B.

OESTRIN

Let us consider *oestrin* first. Secreted by the ovarian follicles, it has a periodic stimulant action on the endometrium of the uterus, greatest in the first half of each intermenstrual phase. But it also has a vegetative action on the growth of the genital organs. This is seen particularly at puberty, when, in consequence of the development of egg-bearing follicles and the appearance of oestrin, the genital organs grow from the infantile to the adult condition. Hence we can at once visualise two therapeutic uses for oestrin: (1) to initiate or restore the normal menstrual cycle; and (2) to bring about development of organs which are under-developed.

One must realise, however, that to produce real effects with ovarian hormones, we must use much bigger doses than was at first envisaged. When I was associated (in the minor capacity of operating surgeon) with Parkes and Zuckerman in their experiments with oestrin, I was able to see at first hand the evidence that enabled Parkes to calculate that, from the weight of the adult woman as compared with the weight of a baboon, the dosage necessary for the adult woman would be in the neighbourhood of half a million mouse units. This surprisingly accurate forecast has been, as we shall see, strikingly corroborated by the work of Kaufmann.

Now 500,000 mouse units of oestrin, as it was then prepared, was an extremely costly dose and the next step towards the effective use of the remedy came from the chemists, the most valuable work in this country being contributed by Prof. E. C. Dodds. The first compound isolated in the crystalline form was found by Doisy and proved to be keto-hydroxy oestrin. All sorts of derivatives were developed and investigated, and among the few I need mention here comes di-hydro oestrin, which is produced by hydrogenation of oestrin. This substance is five times as active as keto-hydroxy oestrin and one gramme of the crystalline substance equals 50 million international units, as compared with 10 million for the keto-hydroxy oestrin. The manufacturing chemists have supplied an oily solution of di-hydro oestrin benzoate in ampoule form, each 1 c.cm. ampoule being equal to 250,000 international units.

This di-hydro oestrin is allied chemically to certain hydrocarbons containing the phenanthrene ring, some of whose derivatives are cancer producing—as in tar cancer. And we may think for a moment on the similarity between oestrus manifestations (e.g., squamous-celled proliferation in the vagina) and the formation of cancer. But we have been reassured that carcinogenesis is not a practical likelihood from the use of oestrin derivatives supplied by the various firms of chemists.

Through the work of such firms as British Drug Houses, Organon, and Schering, we now have, available for therapeutic use, oestrin in convenient bulk for administration in doses of 1000, 10,000, or 100,000 international units. At the same time one cannot help regretting the fact that there are on the market all sorts of preparations with wonderful names, but without any clear indication of the dosage in any standard unit, and without any accurate indication of the specific hormone on which their action is supposed to depend. For myself I can see no value in such preparations and do not think any useful advance in knowledge or in therapeutic benefit will come from their employment. Furthermore, it must be remembered that oral administration of even the best of the hormone preparations is about one-thirtieth as effective as intramuscular injection. As for the dry gland preparations (except thyroid), and the plurigland blunderbuss tablets, and so forth, they are, relatively speaking, useless.

And now to the consideration of the practical use of hormone preparations. Perhaps the most striking case is that in which menstruation has been restored in a woman who has for some reason or other developed secondary amenorrhœa. Kaufmann of Berlin has produced the most notable work on this subject and he says categorically: "with few exceptions I succeeded in producing true menstrual bleeding every time in 40 patients." By true menstrual bleeding he means normal menstruation from a normally proliferated endometrium as demonstrated

by curetting. His technique is to give on the first, fourth, eighth, eleventh, and fifteenth day of the month 250,000 international units of oestrin. Then a pause of three days. Then 7 rabbit units of corpus luteum hormone (progesterin) daily for five days. Menstruation should start a day or so later and can be expected with fair confidence even in a castrated girl.

At St. Mary's Hospital we have not been quite so successful; but about half the cases have responded favourably. Here we do not give the full treatment as recommended by Kaufmann but, following the suggestion of other workers in this country, have reduced the dose of corpus luteum hormone from 7 to 1 rabbit unit.

Now what happens when treatment is stopped? In the castrate woman as a rule nothing; but in the case of secondary amenorrhœa regular spontaneous menstruation may take place for several months. Where there has been severe or prolonged disturbance of the ovarian cycle it is preferable to give the treatment over two or three months, and even then amenorrhœa is likely to reappear after perhaps a few months of normal menstruation.

In young women who have had the misfortune to be castrated it is of course unnecessary to produce menstruation if the aim is merely the relief of their symptoms. Such women may have very severe "flushes," sweats, and the like. In these cases and in women who have severe menopausal symptoms at the natural age, it is said that most striking therapeutic results can be secured. In such circumstances Kaufmann recommends big doses for the first two weeks, 500,000 international units to be given twice weekly. Then the dose should be reduced to 100,000 units weekly. And, I imagine, still further reduction could then be tried. After three months this treatment is suspended.

One other menopausal symptom occurring either in castrate women or after the natural menopause and deserving of individual consideration is itching. This symptom, occasionally so very troublesome, may be vulval or general, and usually responds well to treatment with oestrin. The first few doses, however, may aggravate the condition. So be prepared for such a temporary set-back and continue with the treatment. But you must give big doses. I suggest that 100,000 units of some preparation of oestrin be given twice weekly. Even without making use of these massive doses, many menopausal cases improve considerably on doses of 10,000 units of oestrin weekly. Flushes particularly are greatly benefited and mental depression often relieved.

My next mention of oestrin for therapeutic purposes is in reference to scanty menstruation in young women. Oestrin in doses of 250,000 international units should be given on the third, sixth, ninth, and twelfth days following a period—i.e., in the proliferative phase. Kaufmann states that "if during treatment normally marked bleeding is produced, then, after an average of three courses of treatment, we may expect bleeding to remain normal after the cessation of treatment."

Oestrin has also been used in attempts to induce labour, but is not valuable for this. But Leyland Robinson and his colleagues report (Brit. Med. Jour., 1935, i., 749) that it is extremely useful in preparing a uterus which contains a carneous mole or a dead pregnancy to respond to the stimulation of pituitary extract and quinine and so to expel its contents. For this purpose they treated cases with doses varying from 100,000 to 3,000,000 units of oestrin and about four days later gave the quinine and pituitary.

Their results were satisfactory and their findings suggested that oestrin may perhaps prove useful in the treatment of primary uterine inertia. But it is too early to speak of this yet. Oestrin is also suggested for vomiting of pregnancy and 10,000 units three times a week has been indicated as a suitable dosage.

Sterility and menstrual headache have been spoken of as responding to treatment by oestrin, but I have no personal experience of this. But I have tried it for vulvo-vaginitis in young children as suggested by Nabarro and Signy in THE LANCET of March 16th, 1935, and thought that it did good.

It may have been noticed that though I have dealt with reproduction of menstruation in cases of secondary amenorrhœa, I have not mentioned oestrin and progestin therapy for primary amenorrhœa and genital hypoplasia. If anybody desires to treat such cases, the technique for the treatment of secondary amenorrhœa is adopted and is repeated over and over again. But it is a long and a tedious and expensive business.

PROGESTIN

Another therapeutic use of the ovarian hormones is that of the corpus luteum hormone for the control of irregular or excessive uterine hæmorrhage. We used to call this hæmorrhage the result of "endometritis," but we now believe it is due to cystic hyperplasia of the endometrium resulting from excessive oestrin production. The modern conception is that the ripe and ripening follicles fail to rupture, and so fail to become converted into corpora lutea. Therefore they continue to produce oestrin in excess and no "progestin" appears. This endometrial condition can be produced experimentally in castrated women, but very large doses of oestrin are required—about 5 million units spread over eight weeks. And to cure the experimental condition thus produced, very large doses of corpus luteum hormone are required—up to 90 rabbit units. Clinically, however, smaller doses work well and 20 rabbit units, spread over six days, may be expected to succeed.

Therefore the obvious clinical treatment is to give corpus luteum hormone, and on Kaufmann's recommendation 15 rabbit units spread over five days may be taken as a reasonable standard. However, some cases do not respond to large or small doses. These cases appear usually to have a large follicular cyst, resection of which may reasonably be entertained.

This is a convenient moment to mention the difficulty that the clinician experiences when dealing with all these "units." Roughly speaking one rat unit = 5 mouse units = 25 international units. But unfortunately this is by no means always true, since certain hormones standardised first against mice and then against rats will not conform to the above standard. And rabbit units are different again! So the clinician is compelled to memorise arbitrary doses of so many international units for this and so many rabbit units for that and so on. Personally I find it all very difficult. To illustrate this, I have already given Kaufmann's recommendation for the treatment of cystic endometrial hyperplasia causing menorrhagia. For the same condition the Organon firm recommend only "five rabbit units spread over several days just before the flow is expected." And, as we shall see, another line of treatment is to give not corpus luteum hormone itself, but the anterior pituitary hormone which stimulates the production of corpus luteum which is usually standardised in rat units.

After this digression I must return to the corpus luteum hormone. In addition to menorrhagia, cases of habitual abortion do very well under this remedy. Of course it is necessary to eliminate any cause such as syphilis, nephritis, a badly retroflexed uterus,

or an extensive cervical tear. And one must give the necessary advice as to avoidance of muscular effort, coitus, &c. But when this is done cases which have had a series of miscarriages can often, I might say usually, be brought safely to term by the bi-weekly intramuscular injection of 1 rabbit unit of corpus luteum hormone from as early a date in pregnancy as possible to the thirty-second week. We have found it advisable to stop the injections then, since otherwise some women see fit to try to prolong the period of gestation beyond the normal 40 weeks.

PROLAN B

But it is expensive. Each ampoule (of 2 rabbit units) costs about half a guinea and in view of the expense, and because until recently corpus luteum hormone preparations were unreliable and badly standardised, we at St. Mary's have been using as an alternative the gonadotropic hormone from the anterior part of the pituitary gland. We have aimed at using prolan B, but nothing can be gained from discussing whether this is radically different from prolan A. The commercial preparations we have used are Antuitrin S (Parke Davis) or Pregnyl (Organon).

We have treated a large number of cases of habitual miscarriage with antuitrin S with most gratifying results. Our dosage has been 1 c.cm. intramuscularly twice a week. Now it is believed that antuitrin S loses its activity very rapidly and our success may have depended on the large number of cases treated requiring constantly renewed supplies of the preparation so that it was always fairly recently prepared. For the practitioner using it only occasionally antuitrin S cannot be recommended since it is probably inert after a short time of storage. It may be shown by experience that pregnyl is therefore preferable for use in individual cases since its preparation and method of dispensing make for the retention of its active properties. If therefore any of you propose to try pregnyl for any cases of habitual miscarriage without any ascertainable cause, I recommend you to give 30 rat units intramuscularly twice weekly at first and to increase to 100 such units if no unpleasant symptoms are produced. Let the treatment be started as early in pregnancy as possible and be continued until the thirty-second week. And now let me refer to the use of gonadotropic hormone as an alternative to using corpus luteum hormone in the treatment of menorrhagia in women of, say, 35 years of age. A suggested line of treatment is 100 rat units of this type of hormone (say pregnyl) intramuscularly three times in the ten days before a period and 30 rat units daily during that time.

Finally cases of spasmodic dysmenorrhœa may be presumed to be due to excessive and colicky uterine action. Theoretically uterine contractions should be diminished by the action of the corpus luteum. Therefore it has been recommended that cases of dysmenorrhœa in young women should be treated by the administration of corpus luteum hormone in doses of, say, 2 rabbit units two days before the pain and repeated on the first day; or the corpus luteum stimulating hormone may be used e.g., pregnyl 30 rat units daily, starting two days before the pain is expected.

SUMMARY

To recapitulate. (1) For severe menopausal symptoms in a young oophorectomised woman: 500,000 international units of oestrin twice weekly reduced later to 100,000 units weekly. Stop at the end of three months. (2) For less severe menopause cases: 10,000 units of oestrin weekly. (3) For itching at the menopause: 100,000 units of

œstrin twice weekly. (4) For scanty menstruation in young women: 250,000 units on third, sixth, ninth, and twelfth days following a period. Three courses of treatment in all. (5) To induce labour in cases of retained dead pregnancy: 500,000 units of œstrin split into 5 doses with intervals of eight hours followed four days later by quinine sulphate, 3 doses of ten grains at hourly intervals, and 0.5 c.cm. of pituitrin, 4 doses at hourly intervals. (6) For vomiting of pregnancy: 10,000 units of œstrin thrice weekly. But I have no personal experience of the results of this treatment. (7) For "metropathia hæmorrhagica"—a period of amenorrhœa followed by prolonged profuse uterine hæmorrhage—and for menorrhagia in young women: 15 rabbit units of corpus luteum hormone spread over the five days before a period if there is any regularity, or given during the time of hæmor-

rhage in other cases. Alternatively: the gonadotropic hormone preparations such as pregnyl, 3 or more doses of 100 rat units, in the ten days preceding the flow (if regular) or 1 c.cm. of antuitrin S twice weekly. (8) Habitual abortion: 1 rabbit unit of corpus luteum hormone or 1 c.cm. of antuitrin S twice weekly from say the eighth to the thirty-second week of gestation. As an alternative to antuitrin S, the preparation pregnyl, 30 rat units twice weekly, increased to 100 units twice weekly if no unpleasant symptoms are produced. (9) Spasmodic dysmenorrhœa: corpus luteum hormone, 2 rabbit units two days before the pain and 2 more rabbit units at the onset of menstruation. Alternatively, one of the prolan B preparations (gonadotropic hormone) 30 rat units daily, starting two days before the pain is expected.

OPENING OF THE MEDICAL SCHOOLS

THIS week has seen the beginning of the academic year at some of the schools of medicine and allied sciences in London. Below we print extracts from Sir Gowland Hopkins's address to students at the College of the Pharmaceutical Society, and from "Ian Hay's" address at Westminster Hospital.

PREPARATION OF THE PHARMACIST

BY SIR GOWLAND HOPKINS, O.M., F.R.C.P., P.R.S.
PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF CAMBRIDGE

THE more responsible the calling the higher should be its standards, alike in education and in practice, and British pharmacy is surely fortunate in possessing, in the Pharmaceutical Society of London, a representative body of which the aim—to-day so successfully fulfilled—has been to maintain standards which make for the dignity of the calling, and earn for it the respect of the public.

I would like to speak first in praise of the Society's educational policy, of which the thoroughness and efficiency are remarkable. The standards it imposes are undeniably high, and I am aware that there are some at least who, placing emphasis on the special conditions in which the average pharmacist in this country practises his calling and the peculiar commercial services which the British public is accustomed to expect from him, maintain that such extensive educational demands—on the scientific side at any rate—may outrun the needs of practice, and impose an undue burden on the efforts and time of the beginner. If among my audience there chance to be any who take this standpoint, I hope they will bear with me while I advocate a view which is entirely different.

Educational problems as a whole are, of course, too big to be discussed here; but there is an aspect of policy I would like you to consider as being of importance in the general tenor of my remarks. How soon should the vocational element enter into educational courses? It is often urged that the true function of education is to train the mind to think rightly rather than to store it with facts. There is of course much truth in this, especially in the case of children and adolescents. But technical or vocational teaching has to follow at some moment, and the greater the knowledge required for a chosen career the longer the time which must be spent upon it. Vocational needs must not make the teaching

of a science so one-sided that the student risks missing the intellectual stimulus which the great generalisations of science provide. I am personally sure however that the skilful teacher of students whose ultimate aim is to apply science in practice can illustrate general principles adequately while selecting facts and aspects which have a permanent vocational value.

For the encouragement of the average student it is important that the reality of this permanent value should be part of his faith. I have been in touch with medical students for more than half a century, and have taught them for a great part of that period. Throughout I have realised, as every teacher of the pre-clinical sciences has to realise, that save for a select group, which one must admit is growing larger to-day, medical students are convinced that the three years spent on their pre-clinical studies represent a painful delay in their approach to realities, which only come, they believe, when contact with patients is reached. I have no doubt that many students of pharmacy, though their ultimate aims are different, have analogous feelings. This attitude is after all based on an innate characteristic of the Anglo-Saxon race which loves action better than thought, and practice better than theory. It is a quality which has served the race well politically, for in politics and national adventures it is character that counts, and, as we were long ago reminded, action may be hampered by the "pale caste of thought." But this same quality has sometimes kept us from being in the van of intellectual, and, no less, of commercial progress. It was because it had become really scientific that the medical knowledge of another country received for a long period, and up to the time of the war, the greatest respect of the world, and it was because its chemists were so thoroughly trained in theory that the same country obtained, among other similar advantages, a long lead in the production of synthetic drugs, which, rightly or wrongly, brought it enormous profits. That same country has now replaced its former respect for intellectual effort by the crudest form of nationalism, which ignores the claims of the intellect. We ourselves can profit just now in some activities quite legitimately by cultivating the earlier enthusiasms of that country while it is otherwise engaged.

All that I have so far said has been in preparation for a more succinct statement of certain articles of my personal faith.

First I believe that for the student of pharmacy, no less than for the student of medicine, the chief

gain from the science teaching which must precede practical activities is in the scientific attitude of mind which it creates, and in the special intellectual background it provides which, even when a mass of detail is forgotten, remains a valuable possession. But I also believe that when teachers and examiners are wise, this most desirable result can be obtained by teaching which is essentially vocational, and largely confined to aspects of scientific knowledge which are of permanent and practical value.

A more recently acquired article of faith with me is one which the present occasion has established. I have been reading the educational pages in the Society's calendar, and, while recognising my limitations as a critic, I feel justified in my belief that those pages reveal a policy based upon sound judgment. The syllabuses provide, in my opinion, just that amount of vocational reference which is so encouraging to the student, without lowering the intellectual value of the courses.

I certainly find myself among those who wholly approve of those additions which are now about to take their place in the curriculum. That the biological teaching should at this time be extended on its animal side is only logical. When vegetable drugs and preparations of vegetable origin bulked so largely in the pharmacopoeia, the prominence of botany in the curriculum was justified. With the immense development of glandular or hormonal therapy conditions have altered. It is clearly desirable that all who may have concern with the preparation and the standardising of organic therapeutic preparations and the distribution of the countless proprietary preparations of this class, should possess, no less than those who prescribe them, an adequate knowledge of the nature and functions of the various organs from which they are derived, as well as of the bodily functions they control.

Scarcely different is the case of vitamins; indeed it is nearly, if not quite, justifiable to look upon a vitamin as a hormone which the body cannot make for itself, or on a hormone as a vitamin which it does make for itself.

The trouble indeed for all of us who, from any standpoint, have to think about or deal with hormones and vitamins, whether as physiologist, biochemist, clinician, or pharmacist, is the present great complexity in the facts concerning them. Knowledge concerning the control of the body by a multiplicity of hormones with complicated inter-relations is growing daily, and the literature dealing with research on vitamins has of late contained as many as a thousand papers in a year. Only the specialist can deal with such an output; but the fact that substances of the kind are intruding into therapeutics in such an overwhelming way makes it highly desirable that the pharmacist should be aware of the essential facts relating to their origin, distribution, and action, as well as full acquaintance with their chemical properties. It is for this reason that I think the introduction of animal physiology into the courses of the college is so justifiable and so timely. In thus widening the ground of study those responsible have shown themselves to be courageous as well as wise.

Students who are about to begin their college courses may be feeling to-day that they have heavy tasks ahead; but one may remark here that all who hereafter obtain a major qualification in pharmacy will have whatever satisfaction is involved in knowing that the difference between their own scientific training and that of the average medical student is approaching a vanishing-point.

I suppose that any who harbour doubts concerning the practical value to the pharmaceutical calling at large of a somewhat exacting scientific curriculum may also be inclined to think that the encouragement of research is something remote from the Society's essential functions, and may even feel that the expenditure it involves is not justified. If that view has to-day any supporters I should be very happy if any words of mine could modify it.

I am one of those—and they are many—who believe that in every centre where science is taught research should be active. It is no theoretical view, but a belief based upon wide experience that the pursuance of research within a department vitalises its teaching. It compels the teacher to keep in touch with progress, and keeps his mind alert. It creates an atmosphere from which every student directly and indirectly benefits. Where research is absent teaching is apt to become stereotyped, unprogressive, and, very often, dull. All concerned I think, whatever they may feel about the amount of college teaching to be desired, will wish that whatever is taught should be taught well.

Apart from this influence of research upon teaching, the publication of original work from any department awakens the interest of the scientific world in that department, makes it known and gives it distinction.

If anyone were inclined to say to me at this point "you have been speaking as an idealist, ignoring as idealists are apt to do the many problems and issues which dominate practical life," I should answer that policies which seem idealistic to-day are apt to become realistic enough to-morrow. In these times of social and economic changes only one prophecy can be safely made concerning the future of pharmaceutical practice in this country—namely, that it too will suffer changes.

Many of the younger members of the calling look, I am sure, to its becoming, in a more complete and secure sense than now, a profession. If trade be a calling in which material goods are sold and a profession one in which knowledge is sold—and this seems to be one essential difference between them—then I am sure that the professional side of pharmacy is fated greatly to increase in this country.

It is difficult now as always for those who serve the public to avoid supplying it with what it demands. The general public to-day, and not its humbler sections alone, is for the most part too ignorant to be protected from the influence of the advertisements incessantly before its eyes, which proclaim the supposed merits of a crowd of quack nostrums or expensive proprietary articles of little real value. There are many individual pharmacists to-day who I know do their best to protect it from such, and there are committees in being to-day which are considering possible remedies for the evil. But the problem involved in combating it, whether by State action or otherwise, is an extremely difficult one, as all who face it come to realise.

But biological science is gaining a foothold in general education. It is beginning in schools and is increasing its influence in the universities. The time is not far distant when even average members of the community will know much more about their bodies and their bodily functions than they know to-day, and will no longer display the faith which is born of ignorance. When ill they will of course go to the medical man for diagnosis and for guidance, but I believe that there are matters concerning which they will seek knowledge from the pharmacist to an increasing extent, knowing that it will be knowledge based on scientific truth.

I will even venture to suggest that owing to the increasing specialisation in knowledge and its applications which modern progress demands, the future may see certain readjustments in medical practice which will make it easier for the British pharmacist to assume that more definitely professional status which he now occupies in certain other countries. I touch here, however, on difficult and delicate ground. It would be idle to speculate further on lines such as these; we can but very imperfectly foresee the march of events. But of this I am sure: the status of practical pharmacy in this country will rise with the rise in its standards of education.

THE PRIVILEGED PROFESSION

By MAJOR JOHN HAY BEITH, C.B.E., M.C.

I CANNOT help feeling that to-day human relationships are in the melting-pot. The world is being dehumanised: everywhere the machine is taking the place of the man—or, worse still, the man himself is being practically turned into a machine. From sausages to motor-cars and from motor-cars to wrist-watches, things are now manufactured by a subdivision of labour so elaborate that a man's daily work consists in making one simple muscular movement thousands of times over. To the man that means two things. It makes it unnecessary for him to learn a skilled trade, so that he is deprived of the character-forming processes of education; and it takes away from him the only true incentive to labour, the only true reward of labour—the pride of the creator, the joy of seeing a piece of work begun, continued, and ended by one's own hands. That is gone, and with it has gone a certain percentage of the romance of life and of the humanity of the human family.

How far are these modern tendencies going to affect your profession? How much is the art of healing going to be affected by such things as the mechanisation of human life and the inevitable reactions which must follow in its train?

To that I should reply, very little—less than in any other profession perhaps—and for certain definite reasons.

The first and most important reason is that you cannot mechanise medicine—or surgery, for that matter. The human material upon which you have to work presents too many variations. Your domain will be the very last for the robot to conquer. We shall never see an operating theatre, for example, run on the lines of a Chicago meat-packing establishment—a row of eminent surgeons each making one cut in a different place!

Secondly, you are comparatively immune from the craze for self-expression—or self-advertisement—which is the natural consequence of these tendencies, because you have always safeguarded yourselves as a profession against that kind of thing. It is a sacred tradition of your calling that an individual member of it must never seek personal publicity, or advertise himself in any way. Marvels of successful research may be achieved, miracles of healing may be performed, but the credit will go, as it always has gone, to the profession as a whole and not to the individual—just as in the Great War the British flying men, whenever a battle in the air was won, chalked up the achievement not to the account of this pilot or that, but to the greater glory of the Royal Air Force as a whole. That is a noble tradition. Of course, if a medical man feels the urge for publicity

too strong for him, he has his remedy; he can always go to the market-place and extract teeth or sell quack nostrums to the music of a brass band. But he must go outside the profession to do it.

And then thirdly, the medical profession is one of the few where efficiency and thoroughness, and nothing but efficiency and thoroughness, count. There are no substitutes. In commerce we are told it pays to advertise. That is true; if you advertise hard enough you can sell almost anything. But fortunately that sort of thing is no good to you. If a man dies under your hands, we'll say, by reason of your ignorance of your job, no publicity campaign in the world is ever going to persuade him that he is still alive. So that is that!

Still, as we have already agreed, professional efficiency is not quite everything. You must know not only how to heal people, but how to handle them as well. And here I may be able to give you a few hints. You see, I have never been a doctor, but I have occasionally been a patient; and I agree with you, right away, that patients are a most unreasonable tribe of people—a curse, in fact. You can divide them into many classes, but three will suffice here:—

1. People who are really ill. We need say no more about these, because they give little or no trouble.

2. Patients who are rather ill, but do not believe in doctors, and tell you so quite frankly. You know the man who says to his medical adviser:—

"I only called you in because my wife insisted on it. I know as well as you do that the whole medical business is mere mumbo-jumbo; so don't start taking my blood pressure or doing any conjuring tricks with thermometers and stop-watches. I know how my inside works much better than you do, because it's my inside and not yours. You can leave me some medicine if you like, just to save your face; but I warn you I shall probably throw it out of the window."

That's the bluff, honest, hearty type of patient, the type that has made the name of Englishmen respected all over the world. Well, the simplest and most profitable way to handle this individual is to employ the soft answer. You say:—

"My dear fellow, I agree with every word you utter. Of course, you are quite right; all medicine is nine parts faith and one part colouring matter. You and I both know that, so there is not the slightest use in my prescribing for you in the ordinary way. If I may say so, it is a treat to encounter a patient with whom a doctor can be absolutely frank—a patient who doesn't want things wrapped up in meaningless phrases. You, as of course you probably know without my telling you, are suffering from . . ."

Here you give the name of his disease—in Latin, two longish words, with a false concord thrown in. You add a few scientific terms about reflexes and secretions, and so on, and wind up, if possible, with an impromptu chemical formula. After that, he will simply eat out of your hand.

3. Then we come to a third class of patient—the patient who thinks he is going to die forthwith, if not sooner, and has to be cheered up—or, as they say in a bigger and brighter land than this, kidded along. In that connexion I cannot resist calling, or recalling, to your notice one of W. W. Jacob's stories about that immortal trio, old Sam, Peter Russet, and Ginger Dick. I want to read you an extract. Sam, you may remember, was taken ill.

"And," continues the Night Watchman, who tells the story, "like most 'ealthy men who get a little something the matter with 'em, 'e made sure 'e was dying. 'E sent Peter out for the doctor, and in about 'arf an hour Peter

came back with a sandy-haired young man with red eyelids and a black bag. 'Am I dying, sir?' ses Sam, after the doctor had listened to 'is lungs and 'is 'art, and prodded 'im all over. "We're all dying," ses the doctor—"only some of us'll go off sooner than the others." Peter and Ginger Dick took turns to be with Sam that morning, but in the afternoon the landlady's mother came up to look arter 'im a bit. She sat on a chair by the side of 'is bed and tried to amuse 'im by telling 'im all the death-beds she'd been at, and partikler of one man, the living image of Sam, who passed away in his sleep. It was past ten o'clock when Peter and Ginger came 'ome, but they found poor Sam still awake and sitting up in bed propping 'is eyes open with 'is finger."

Well, that's a good example of how not to do it. What a patient of any kind wants is to be reassured; and that is where technical knowledge will not avail you so much as a cheerful presence and a confident manner. And here, speaking from my experience as a patient, may I drop a hint to future G.P.'s? Humanity fears one thing above all others—the unknown. What frightenes a patient most of all is to have nothing definitely wrong with him. Once a definite cause has been assigned to his ailment, once you have hung a label on it marked in plain figures, and given him something physical to hold on to, he will endure almost anything. So if you can, be explicit with him upon this point, even though you may not have the slightest idea what is the matter with him. Tell him something—anything that will keep his imagination from soaring into the regions of unhealthy speculation. Anything will do; a man is never frightened of a thing he knows all about, or thinks he knows. It is a good plan sometimes to be symbolic—to illustrate the patient's condition, or supposed condition, by some mechanical analogy. You can refer to trouble in his engine-room, or explain that his dynamo requires tuning up, or his accumulators recharging, or that an overstrained spring must be relaxed. Something concrete like that—something he can bite on. Tell him that he has a Rolls-Royce body, but that his petrol pressure is faulty. That will cheer him up much more than to tell him baldly that his malady is functional and not organic. It is a strange thing, the amount of solid comfort a nervous person can derive from having his interior compared to that of a motor-car; but the comfort is there—especially if you tell him he's a Rolls-Royce.

In other words, a good doctor must not only be a good doctor, he must be a good propagandist. We need not go all the way with Samuel Butler, who tells a story somewhere of a man who swallowed a doctor's prescription in the belief that it was an actual medicine, and was immediately cured of an illness; but believe me, the personal touch does count, all the time.

Now I have rambled on nearly long enough. But before I sit down, I want to explain at last why I have selected this title, the Privileged Profession, for my discourse.

The reason is this. The doctor is a privileged person because he enjoys certain privileges denied to the majority of men. He is automatically and simultaneously not only his patient's professional adviser, but his personal friend. A layman may have professional contact with all sorts of professional people; and while respecting them in their professional capacity profoundly, he may dislike them intensely as individuals. I forbear to particularise, except to hint that perhaps you may sometimes be tempted to regard your family lawyer as a bore, or your rector as a bit of a prig, or your stockbroker as a

dangerous crook. But nobody ever disliked his doctor. (I am not referring to dentists, of course.) If you are a man's doctor you are his friend too—and that makes the doctor's profession a unique profession.

The family doctor is a sort of Jekyll and Hyde—or better still, a sort of combined Laurel and Hardy. In one capacity he is just a friend and neighbour, with a golf handicap of 12 (which ought to be 15) and a quite incurable passion for going three no trumps upon an inadequate hand. He is just one of ourselves.

Of course we may be so healthy that the very existence of the healing art is entirely unrealised by us. But time will cure this. In the end, sooner or later, we all come to recognise the doctor's existence—and to discover him in his other capacity.

Now we behold a man transformed. Indeed, he is not a man at all; he is a divinity. We implore his presence; we hail his coming with gratitude and relief, as a frightened child hails the entry of some one into a dark room with a lighted lamp. He takes immediate and entire charge of the situation. He orders us about, and we obey his decrees without question and with trembling eagerness. His presence calms our fears, soothes our pain, and restores our hope.

In due course, when he has healed our sickness, or saved our child, and everybody is growing convalescent and fractious, he reverts to his former status—the status of an agreeable table companion, or an unreliable partner in a foursome, or an amiable gossip. In other words, he is just a neighbour again. But down at the bottom of our hearts remains, and always will remain, the memory of that hour when the black chasm opened at our feet, and we held on to his calm and steady hand and begged him to pull us (or somebody else) back to safety—and he did not fail us.

The doctor is one of our few indispensables in life. He launches us into the world. Upon our voyage therethrough he is periodically summoned on board to assist us in that most delicate operation known as "executing repairs while under steam." And when the end comes at last, and the failing machinery refuses any longer to obey the calls from the bridge, it is he who takes the wheel and pilots us with tenderness and skill to our last anchorage. That seems to me a rather fine privilege.

And there is one other, denied to most of us. In most trades and professions you have to establish your bona fides in some definite way. If you apply for a job, you must produce written references and testimonials. In business transactions people expect estimates and contracts. But if you are a doctor in this country you have only to put up a brass plate on your gate with your name and degree on it, and people will accept you as a matter of course. They will believe your diagnosis, swallow your medicine, and take the items of your bill on trust. They won't pay it, but they won't dispute it. And more than that. They will receive you into the intimacy of their family life; they will leave you alone with their wives and daughters, and entrust you with all that is domestically sacred to them, without question. What exactly does this signify? It signifies in the first place that an English medical degree and an English hospital training are good enough for anybody, and in the second that an English doctor is an English gentleman, anywhere. For generations that tradition has been passed down, and it is your privilege—your last and greatest privilege—to uphold it.

CORRESPONDENCE

FORCEPS

To the Editor of THE LANCET

SIR.—Mr. Wrigley has done a service in drawing attention to the danger of the long forceps commonly in use, but surely he goes too far in wishing to discard them altogether. He admits that in most of the cases where he applied forceps the patient would have delivered herself if left alone, and in hospitals such patients are usually allowed to do so. These are really normal cases, where the low forceps operation is employed to hasten the delivery.

During the year 1934, 211 cases of either contracted pelvis or occipito-posterior position were admitted to the unit of the Glasgow Royal Maternity Hospital, to which I am attached; 109 of these had a spontaneous delivery—a higher proportion than in Mr. Wrigley's series, which consisted presumably mainly of normal cases—with one stillbirth; 44 cases had Caesarean section, with no stillbirth; and 58 had delivery by forceps with 7 stillbirths. There was no maternal death. The last group consists of cases of minor degrees of disproportion and of occipito-posterior position, where there is no clear indication for Caesarean section, so that it will continue to exist despite antenatal care. Such cases need skilled intranatal care, which involves, in many, manipulation of the foetus and delivery by long forceps. The delivery cannot be effected in such cases by short forceps. Although Mr. Wrigley states that "to-day there should but rarely be the necessity to resort to any but the low forceps operation, which consists in the lifting of the foetal head past the perineum," he himself used the long forceps in one out of three occipito-posterior cases.

In the same period, 15 cases of "failed forceps" were admitted to this unit. In only three was Caesarean section indicated in the early stages of labour. Three of the remaining 12 had a spontaneous delivery, and nine delivery by forceps. There were two maternal deaths and six stillbirths. These results compare very unfavourably with the hospital figures already quoted for a similar type of case, and show that the crux of the matter is skilled judgment during labour in each individual case. In the hospital group of 58 cases delivery was effected by forceps because of maternal or foetal distress; in my opinion, delivery by the long axis traction forceps is the most efficient and safest treatment in this type of case, where the delivery could not have been effected by the short forceps. Mr. Wrigley advocates "the anaesthetisation of the patient and a thorough examination to ascertain the cause," but does not indicate the treatment in such cases where short forceps are useless.

His suggestion that the student should be instructed in the use of the short forceps for low forceps delivery is a sound one. It is most important for the student to be impressed with the necessity for post-graduate training before he is competent to deal with complicated cases.

I am, Sir, yours faithfully,

Glasgow, Sept. 28th.

DUGALD BAIRD.

To the Editor of THE LANCET

SIR.—I was much interested in Mr. Wrigley's advocacy of the short curved forceps for dealing with that very large proportion of all forceps deliveries which is undertaken for delay in the second stage with the head on or partly on the perineum. I believe

that the short forceps are now almost unknown in modern hospital practice, but among the voiceless general practitioners they must still survive, especially among those who, like myself, have inherited a family practice and the instruments that formerly pertained to it.

I have carried a pair of short curved forceps very like those figured by Mr. Wrigley for over 30 years, and regard them as perhaps my most precious instrument. I have used them on numberless occasions to terminate a tedious second stage when the pains are too weak to overcome unaided the resistance at the outlet in a reasonable time. They weigh one ounce more than Mr. Wrigley's, were made by Messrs. Muir and Thompson many years ago, and have square wooden handles beautifully fitted so that they stand boiling perfectly well. Each blade measures 9½ inches from tip to the bottom of the handle. The handles are shorter and even more convenient. I think, than those of Mr. Wrigley's forceps, in that they have a broad square shoulder grooved with a space to allow a finger to hook over. They can be slipped on very easily in almost any position of the mother without the buttocks necessarily being brought to the edge of the bed and without any deep anaesthesia. Most of my cases have been conducted single-handed with the help of a nurse and a Junker's apparatus. At one time a foot bellows was provided to work this, but latterly more often the pumping of the chloroform has been kept up by the nurse while I am actually using the forceps.

Should the case prove deceptive owing to unsuspected resistance and elongation of a tightly fitting much-moulded head, it is easy enough to remove the short forceps and, if necessary, to apply the powerful axis-traction forceps, which I also carry, in their stead; but this, of course, is a far more formidable operation and not to be lightly undertaken. It is often better to wait.

I am, Sir, yours faithfully,

Hampstead, N.W., Sept. 30th.

J. L. MORTON.

ARTIFICIAL RESPIRATION

To the Editor of THE LANCET

SIR.—In the leading article, entitled *Artificial Respiration on the Spot*, in your issue of July 20th, you deal very fairly with the subject, but omit to mention an old method that has been employed in drowning cases—viz., inversion of the body, which is often of use though it has been unaccountably condemned by some authorities. In the exhaustive Hunterian lectures on the various methods of artificial respiration (March, 1909) Sir A. Keith says, "The effects of inversion I propose to examine when speaking of postural methods." However, the subject seems to have been overlooked or forgotten by the lecturer as I can find no further mention of it. My attention was drawn to the method by the following case. Several years ago I had just left the swimming bath after my daily bathe when I was called back suddenly to attend to a woman said to be drowning in the adjacent women's swimming bath. I found that the patient was a full grown, heavily built girl subject to epilepsy, who had had a fit while swimming in the bath. It did not take long to get her out of the water and I do not think that she was submerged for many minutes. On being brought to the landing I noticed a good deal of fine froth round the mouth, and so I had the girl held up by

the feet, head down, for the froth to escape—quite a torrent. I was astonished at the amount. When it ceased I performed artificial respiration by Silvester's method, and soon had natural respiration established. I think that this was much facilitated and hastened by preliminary clearing the air passages. Schäfer's method cannot empty the passages of froth and water nearly as thoroughly as inversion, and the inspiratory movements begin by drawing water into the air cells.

After death from drowning the pleural cavities are usually found to contain a lot of water transuded from the lungs—probably mostly post mortem. In cases that recover, the same process probably goes on to some extent. What effect has this on recovery? Is the fluid absorbed more or less easily from the pleura than from the lung?

I am, Sir, yours faithfully,

Somaphoro, South Australia.

F. LUCAS BENHAM.

T.A.B. VACCINE FOR GONORRHOEA

To the Editor of THE LANCET

SIR,—I have been using T.A.B. vaccine and gonococcal vaccine intravenously for some years in the treatment of gonorrhoea, and should like, therefore, to issue a word of warning, for experience has modified my first enthusiasm. As the result of this experience I have found that:

(1) Only young adults of excellent physique should be subjected to the treatment.

(2) Such treatment should never be ambulatory. The patient must be confined to bed. This is mentioned but not stressed by Dr. Bartley.

(3) Severe headache and vomiting may be associated with the temperature produced.

(4) With both substances, but particularly with gonococcal vaccine, a negative phase may occur, and precipitate metastatic lesions rather difficult to explain away.

I personally, therefore, now use the method mainly in persistent chronic vesiculitis or prostatitis, and in the resistant urethritis that is occasionally met with in the female. In such conditions the results obtained are often most striking.

Pyrotherapy is such an extremely valuable weapon in our armamentarium that it would be a pity if its reputation were damaged by indiscriminate use.

I am, Sir, yours faithfully,

J. JOHNSTON ABRAHAM.

Queen Anne-street, W., Sept. 28th.

PLASTER TECHNIQUE IN TREATMENT OF FRACTURES

To the Editor of THE LANCET

SIR,—Mr. Pridie is to be congratulated on his clear and concise description of the methods used by Dr. Lorenz Böhler, of Vienna, in the treatment of fractures. After five years' experience of the non-padded plaster-of-Paris cast in the fracture services of Mr. Harry Platt at the Ancoats Hospital and the Manchester Royal Infirmary, I can testify wholeheartedly to those advantages which Mr. Pridie claims for it. On some details regarding the method of application and on the subsequent treatment, I find myself at variance with him, but these are of minor consequence. My fear lies in the possible inference that this is a method of great safety, which can be easily acquired from a written description, and is suitable for adoption by the general practitioner or surgeon who is called upon to treat an occasional fracture only. As pointed out in your editorial (Sept. 28th) the chief danger is "constriction of the limb." From our own experience we have no doubt that the introduction of the non-padded plaster-of-

Paris cast has increased the incidence of circulatory disturbances of varying degrees of severity. This complication is usually, although not invariably, due to faulty technique. If not recognised immediately and suitably dealt with, it is certain to be followed by the most disastrous results. For this reason alone, I believe that for the present the method should be used only in the larger organised fracture clinics. The technique requires a long apprenticeship before it can be used not only artistically, but with safety to the limb of the patient. It will be remembered that the widespread practice of plating fractures in the smaller surgical centres ultimately brought discredit to this branch of surgery. We fear that the non-padded plaster cast may acquire an equal stigma.

The centralisation of fracture treatment in the larger hospitals is proceeding slowly but surely. Until such clinics are everywhere available, I am convinced that it would be wiser to refrain from advocating specialised methods, which, in inexperienced hands, are fraught with danger.

On the advantages of using a stock plaster bandage, such as the Cellona bandage, in preference to bandages made in the plaster department of the hospital clinic, we have an open mind. After a trial of the Cellona bandage in the fracture service of the Manchester Royal Infirmary, we are not yet convinced that it is cheaper or more effective than the bandages made under the direction of an expert plaster sister.

I am, Sir, yours faithfully,

II. OSMOND CLARKE.

Manchester Royal Infirmary, Oct. 1st.

LIPIODOL AS A THERAPEUTIC AGENT

To the Editor of THE LANCET

SIR.—Prof. Harrower's paper in your last issue interested me greatly, because I have recently observed a similar effect in a totally different type of case.

A woman, aged 50, was admitted to St. Mary's Hospital for Women and Children, E., as a case of syringomyelia and syringobulbia. The more striking physical signs were as follows: complete anaesthesia to heat and cold of the feet and legs, with little alteration of other sensation; almost complete anaesthesia of the front of the chest to painful stimuli and to heat and cold. (The anaesthesia here was so complete that the patient arrived at the hospital with the front of her under-vest covered with blood derived from a painless pricking with the pin of a brooch, which had come undone.) There were no notable trophic changes in the skin of the feet; and the gait was relatively little affected. Speech was coherent, but slow as the result of difficult articulation. There was slight anaesthesia of the face to pin-prick, but not to heat and cold. The only other striking sign was severe, right-sided ptosis.

The general characters suggested that this was not a true case of syringomyelia; and blood was sent for the Wassermann reaction. In the interval between the sending of the blood and the receipt of the report, a cisternal puncture was performed. This was done, partly to demonstrate the condition of the theca, and partly for the benefit of a class of students. There was no hope of a good therapeutic result in my mind at the time. The cisternal puncture was performed *secundum artem*, and 4 c.cm. of lipiodol were injected. Radiograms, taken with the patient in the erect position, showed almost the whole of the lipiodol at the bottom of the theca immediately, but there were small globules scattered about at different levels. As the lipiodol had fallen so well, the patient was put back to bed with only one pillow; and, apart from headache of moderate severity, felt little the worse the next day. The surprising finding was that, at the end of 36 hours, the right-sided ptosis had disappeared and has not recurred (two months), although, according to the history, it had been present for at least four months. Furthermore, there was now definite, although defective, appreciation of heat and cold in the feet.

The Wassermann reaction in the blood and cerebro-spinal fluid was strongly positive; and vigorous anti-syphilitic treatment has almost restored the patient to health.

Prof. Harrower attributes the improvement in his two cases to "a chemical inflammation superimposed on the chronic condition." Such an explanation might be applicable to the return of sensation in my patient's feet, but it will not explain the sudden disappearance of the ptosis. It would be most valuable if the mechanism could be elucidated.

I am, Sir, yours faithfully,

Park-square West, N.W., Oct. 1st.

A. PINEY.

INFECTION IN SWIMMING BATHS

To the Editor of THE LANCET

SIR,—In your issue of Sept. 28th (p. 740) you refer to my closure of the swimming baths here on account of scarlet fever, and the following details may be of interest:

A violent outbreak of scarlet fever commenced about August 23rd, which was traced to a dairy in the borough, and from there to a certain farm where it was found that one of the milkers had been milking from August 21st—

23rd (inclusive) with a very sore-throat, but no rash. On August 26th this milker's son was definitely notified as scarlet fever, and on swabbing the throats we found hæmolytic streptococcus Type II. in the milker, his son, and his wife. Hæmolytic streptococcus Type II. was also found in the milk, and in all cases of scarlet fever where the milk supply was the suspected source of infection, whilst in several other cases where the milk could be exonerated Type IV. was found. The number of cases notified was about 350, but from inquiries I have made the number of cases affected must have been close on 1500. Most of the non-notified ones had no rash. It therefore became apparent that there was a risk of such cases, on recovery, using the swimming-baths, and it was for this reason that the baths were closed on Sept. 12th.

I may say that the swimming baths have no proper system of filtration or chlorination. I am, of course, familiar with Dr. Alison Glover's work, but have had strong reasons to suspect the Chelmsford baths as giving rise to cases of sore throat in the past, and I felt that to allow bathers to use them in the present circumstances was not advisable.

I am, Sir, yours faithfully,

J. C. SLEIGH,

Sept. 30th.

Medical Officer of Health, Chelmsford.

PANEL AND CONTRACT PRACTICE

Notification of Tuberculosis in London

THE London insurance committee has asked for a report on the number of deaths from tuberculosis in the county during 1930-33, and whether any (and if so how many) of such deaths were either first reported to the county medical officer by the death returns of the local registrar, or were posthumously notified. Should there be any substantial number the medical benefit subcommittee is to suggest measures to secure earlier notification. The mover of the motion drew attention to the fact that of the counties in England and Wales with the highest incidence of deaths from tuberculosis during the four years in question London is seventh, and as the six worst counties are all in Wales London has the unenviable position of the worst county in England. In 10 per cent. of deaths from tuberculosis, he said, the disease was notified posthumously; sufferers, he urged, should be removed from an environment in which they might be a danger to the rest of the community. A medical member of the committee pointed out some of the problems confronting doctors in relation to the notification of tuberculosis; another while supporting the motion thought that pulmonary tuberculosis should be regarded differently from other forms of tuberculosis in regard to possible infection.

In the four years 1930-33 the average death-rate from tuberculosis (all forms) in the administrative counties of England and Wales was 777 per million. The average deaths per million during the same period for the ten worst counties were: Merioneth (1348), Caernarvonshire (1333), Anglesey (1232), Cardiganshire (1078), Pembrokeshire (1043), Brecknockshire (1022), London (971), Glamorganshire (967), Durham (964), and Northumberland (941). London thus keeps company with seven Welsh and two north-eastern counties. But curiously the ten counties with the lowest death-rates are mainly in the south-east of England; they are East Sussex (628), Isle of Ely (627), Hertfordshire (623), Surrey (617), Oxfordshire (613), Buckinghamshire (605), Wiltshire (589), Rutland (583), Derbyshire (555), and Soke of Peterborough (491).

Comparing London with other county boroughs a less unfavourable result is obtained, for all the

following had a death-rate per million of over 1350—viz., South Shields, Middlesbrough, Gateshead, Bootle, Liverpool, and Salford, while closely following them are Tynemouth, Sunderland, Newcastle-upon-Tyne, and Manchester with over 1250. All these boroughs, except perhaps Salford and Manchester, are seaports; three of the ten boroughs with the lowest death-rates are seaside boroughs—viz., Blackpool, Eastbourne, and Southport.

A Novel "Representation"

The London committee, upon the recommendation of its medical benefit subcommittee, decided to make a representation to the Minister of Health that the continuance on the medical list of a practitioner who is 85 years of age, and deaf, would be prejudicial to the efficiency of the medical service of the insured. The local medical and panel committee and the Minister had already concurred in action under Clause 4 (4) of the terms of service, and notice had been given to the insured persons concerned that the doctor was not in a position adequately to discharge his obligations under the terms of service. This is the first occasion, it appears, on which a representation has been made in such circumstances.

Employing Assistants

Clause 11 (3) (n) of the terms of service lays it down that a doctor shall not, except as a matter of temporary arrangement, employ an assistant to attend his insured patients without the previous consent of the insurance committee, which shall not unreasonably withhold its consent, and in no case without previous consultation with the panel committee. Should the two committees disagree the doctor is entitled to appeal to the Minister for a final decision. Two doctors recently applied for the consent of a committee in the Midlands to their employing assistants. The committee took the view in each case that the applicant ought to secure the services of a doctor as a partner and not engage an assistant in view of the number of insured persons for whom they were responsible and having regard to the distance between the residences and the surgeries. The panel committee was consulted and the doctors in due course complied with the committee's requirements.

OBITUARY

**FRANK CHARLES SHRUBSALL, M.D. Camb.,
F.R.C.P. Lond.**

Dr. Shrubsall, a senior medical officer to the London County Council, died at his home in Hampstead on Sept. 25th at the age of 61. His death came as a shock to his friends, for he had just returned from a holiday in Pembrokeshire reporting himself better for the change, and he was at the County Hall two days before his death.

Frank Charles Shrubsall was educated at Merchant Taylors' School and went up with an entrance scholarship to Clare College, Cambridge, where he took a first class in both parts of the Natural Science Tripos. He entered as a medical student at St. Bartholomew's Hospital, gained the Shuter and Brackenbury medical scholarships, and qualified in

1900. In the following year he became a member of the Royal College of Physicians and was elected to the fellowship in 1912, holding in the meantime house appointments at St. Bart's and Brompton. An only son and never robust, his health gave anxiety to his family from childhood and he was sent on several sea voyages. Thus early in life he came in contact with differing types of men, and this

DR. SHRUBSALL

aroused in him that intense interest in the study of mankind which was to shape his career. In 1904 the British Association met at Cambridge and Shrubsall read a paper comparing the physical characters of hospital patients with those of healthy individuals from the same areas and making suggestions on the influence of selection by disease on the constitution of city populations. This paper not only revealed the bent of his mind and his exceptional gifts of observation, but assured him a position among British anthropologists, and he was elected a member of the committee on anthropometric investigation in the British Isles. He also became secretary to the anthropological section of the Association, an arduous post which he held for 18 years. The new developments in elementary schools initiated by the Education (Administration Provisions) Act of 1907 opened up for him a new and attractive field for scientific study, and in 1907 he read a paper at the Leicester meeting of the Association on anthropometry in relation to the school. At this time also he was lecturing on physiology and anatomy to teachers of physical exercises at the Chelsea Polytechnic, gaining the intimate knowledge of the theory and practice of physical training which helped to determine his life work.

In January, 1909, Shrubsall joined the band of brilliant young experts which Dr. James Kerr was forming to cope with the rapidly expanding medical

services in L.C.C. schools. At first, engaged in the general work of the department, he found an outlet for his special knowledge in a mass of physical measurements of school-children already collected. These he collated and analysed, producing comparative figures of the physique of children in central and suburban areas of London. In 1910 he collaborated with Dr. Jane Gilmour, a Glasgow graduate, in an investigation into the aetiology of rheumatism which not only threw light on the distribution and characters of juvenile rheumatism in London, but led to the marriage of the investigators. The growing activities of the service demanding a measure of specialisation, Shrubsall found himself in charge of the L.C.C. special schools for the mentally and physically defective, the blind, the deaf, the partially sighted, and the hard of hearing. His department also included the reformatory schools under the Home Office. Under the Act of 1914 the L.C.C. became the local authority for mental deficiency, and the great volume of medical work falling upon the council in this connexion was naturally placed under Shrubsall's direction. Similarly, as he was associated with the training and after-care of blind children, the medical care of the blind generally which the Blind Persons Act of 1920 placed upon the L.C.C. came under his direction. And when Dr. James Kerr relinquished his service with the council his work connected with the health of teachers and with medical examinations of every kind at the County Hall was transferred to Shrubsall's department. On Sir John Collie's retirement the medical examination of the council's employees also came under his care. The Local Government Act of 1930 not only added enormously to the number of employees in the council's service, but also led to the transference from poor-law administration of large numbers of mentally defective, blind, and other persons.

Thus at the time of his death Shrubsall had charge of an immense volume of public work of the most responsible kind. His association with the development of the public care of mentally deficient persons from its beginning gave him an unique knowledge of this subject. To him the dull and the defective child constituted educationally one problem, and he was fully in sympathy with the findings of the government committee which was responsible for the Wood report, and which recommended the recognition of the two types as one educationally "retarded" group. He was intimately connected with the recent improvement of methods of care of "problem" children involved in the conception "child guidance." The calls upon his time for educational work on these subjects were very great. He was in constant request for evidence and assistance to government inquiries and advisory committees. He was lecturer in mental deficiency at the Maudsley Hospital; he organised the practical work of the courses in mental deficiency carried on in London for many years by the Central Association for Mental Deficiency, the Board of Education, and the University of London. He was required to give informative talks to associations of justices of the peace both in London and the provinces; he also lectured at the London School of Hygiene and Tropical Medicine. The call for information of this kind led to the preparation, with his colleague, Dr. A. C. Williams, of a text-book on "Mental Deficiency Practice." Shrubsall was one of the most widely travelled and deeply read of his medical contemporaries; he had in the course of his life visited nearly every country in the inhabited globe.

For his presidential address to the anthropological section of the British Association in 1924 at Toronto he returned to the subject which first made his mark 20 years before, but expanded it to include all humanity in time and space. It was entitled "Health and Physique throughout the Centuries," and epitomised his reading and thinking, his travels, and his own original researches, and it attracted much attention. In the years immediately following the war there arose a number of cases of delinquency among children of a new and startling nature. Social workers were puzzled. Investigation showed they were associated with attacks, often missed or misunderstood at the time, of encephalitis lethargica. All these cases, of which there were many hundreds, came under Shruballs' own personal notice and enabled him in contributions to medical journals from 1925-27 to exhibit a clear clinical picture of the results of this disease.

One of those who worked with him writes:—

"Hampered as he was throughout his life by recurrent attacks of bronchial asthma, it is amazing that Shruballs was able to do what he did in scientific research and public service. Humanity was his oyster which he opened, not indeed with sword or lancet, but with a penetrating understanding and an all-embracing affection. He was unsparing of self in his devotion to duty and in his numerous acts of kindness. His loyalty to his friends and his generosity knew no bounds. Where it was a question of giving help to a sorely tried colleague or friend the word 'impossible' did not exist for him. A sudden telephone call and a colleague was despatched to act as deputy in delivering a lecture, while he sped with his friend to see an ailing daughter and to restore peace of mind by wise advice and immediate action. His wide knowledge made him the most entertaining of companions. He loved to meet and learn at first hand from those who had done things

in wild and foreign lands. He could take up the thread of conversation on any topic of real human interest and enrich it from his own store. His deep understanding of the springs of human action rendered him the most tolerant of men. Never did he sit in judgment. Where others would recoil in dismay from a case where disaster had been brought about by apparently disgraceful conduct, Shruballs would see only an occasion for sympathy and help. His official duties brought him constantly into contact with anguish caused by illness or misconduct, and to innumerable human hearts he brought a measure of solace and relief in conditions where all comfort had seemed a vain hope. His love of humanity gave him the power of getting 'underneath the skin' of the most recalcitrant and obstinate of patients or delinquents and in the same way enabled him to make friends everywhere he went. It is recalled that during his student days he was working at a Swiss university for a time. On one occasion he was playing tennis with a partner who imperilled the game by poaching. He took her at last firmly by the elbow, led her to her proper position in the court, and indicating a circle with a sweep of his racket he admonished her with the words 'Sie müssen hier bleiben.' When his work was finished and it was time for him to leave, such was the affection and esteem in which he was held that the entire university assembled at the station chanting in unison as he entered the train 'Sie müssen hier bleiben.' A more recent recollection is of a small party of Scottish students on a fleeting visit to London, sitting in the restaurant at which he habitually lunched. They were very reserved and patently suspicious of their southern surroundings. In a moment Shruballs had penetrated their reserve, put them at ease, and for half an hour he held them spellbound with lore of their own native Aberdeen. Himself the happy physician he brought happiness to others."

PUBLIC HEALTH

Paratyphoid Among a Hospital Staff

OF the typhoid group of diseases Prof. M. Greenwood remarks¹ that he knows no other illnesses in respect of which the evidence of man's theoretical and practical capacity to control them is so cogent. Nevertheless, he concludes, danger still lurks in wait and, in this matter of enteric diseases, central and local health authorities can never afford to relax their vigilance. In one of his yearly records of the state of the public health Sir George Newman pointed out that the major causes of enteric infections, such as polluted water-supplies, having been gradually eliminated there remained the more elusive and less easily controlled factors, such as carriers, contact infection, and contaminated foods. A recent outbreak of paratyphoid-B fever among the staff of the Ipswich and East Suffolk Hospital—for the details of which we are indebted to Dr. A. M. N. Pringle, medical officer of health for Ipswich—provides an apt illustration not only of the dangers which may lurk elusive in unexpected quarters but of the vigilance with which they are countered by the sanitary authority.

When the first patient, a member of the nursing staff, sickened on June 16th, the hospital contained

270 patients in the general wards and 30 in the pay-block. Of these 300 patients only 2 of those warding in the pay-block were infected. The personnel of the institution comprised 6 resident medical officers and 156 nurses, together with a domestic staff of 51 plus 24 day-women, and engineers and porters to the number of 19. The doctors provided 2 cases of paratyphoid fever, the nurses 21, the domestic staff 11, the day-women 1, whilst the engineers and porters escaped entirely. With 3 exceptions those affected were promptly removed to the isolation hospital. As Dr. Pringle says, the incubation period of paratyphoid fever is extremely variable, ranging from a few days to more than three weeks; not only so, but owing to the insidious nature of the invasion in many cases, it is difficult to define. He is satisfied, however, that the infective period in the hospital definitely dated between June 10th and 12th. Two cases, notably severe, occurred after an incubation period of 7 or 8 days; in 28 the period ranged between 9 and 14 days, and in 6 between 16 and 21 days. Dr. Pringle believes that the dates of onset point either to one massive infection or more probably to a series of infections extending at most over 3 days.

The food-supply of the hospital was common to patients and staff, and was cooked in the same kitchen by the same staff, the members of which remained unchanged throughout the month of June.

¹ Epidemics and Crowd-Diseases, London, 1935, p. 137.

The fact that no patients in the general wards were infected ruled out extra-mural contamination of the food-supply; absolved the kitchen staff from a causal standpoint; and constituted a tribute to the cleanly methods observed by the nursing staff within the wards. But although the preparation of meals was common to the whole institution, their distribution was effected in different ways by different people. Meals for patients were placed in food containers by the kitchen staff. The containers were taken to the wards by porters, and the meals distributed by nurses. The exempt engineers and porters distributed their own meals and consumed them apart. On the other hand, the food of all other sections of the staff was distributed to the various messes by maids who also set tables, served, and cleared up. These maids played no part in the service of the general wards. As already mentioned, 2 patients in the pay-block were infected, and it is significant that the patients in this block had the same breakfasts and dinners as their nurses; the medical and nursing staff the same meals at night; and the night nurses the same breakfasts and dinners as the day nurses.

These facts pointed to the probability of the infection of food supplied to these sections of the hospital population by dining-room maids. Nearly half this latter group were infected. It appears that the women-cleaners lunched at the same table but some hours earlier than the nurses' dining-room maids who however handled the same crockery, bread, &c., used by the earlier mess. Amongst the cleaners was a Mrs. B. who was employed in the laboratory. This woman went home ill shortly after her lunch at 9.30 A.M. on June 12th. On her return to the laboratory at the end of July her blood-serum agglutinated paratyphoid B very strongly. Dr. Pringle has no doubt that she suffered an attack of paratyphoid fever, although her stools, when it was possible to examine them, proved negative. A fellow worker of Mrs. B. in the laboratory, a boy, was proved to be excreting paratyphoid-B bacilli in his faeces on June 26th and as late as July 9th. Whether he himself suffered a clinical attack was not substantiated, but that as a carrier he infected his mother and brother between June 8th and 11th seems clear. Further, his professional duties included the decanting of acidophilous milk for an out-patient. Unfortunately, somewhere between June 10th and 12th he also decanted the organisms of paratyphoid with the result that the patient fell ill about June 17th. The source of infection of the two laboratory workers was not traced, but since a few cases of paratyphoid were notified in the town at the end of May and the beginning of June it may be hazarded that the receipt of some infected sample at the laboratory of a large general hospital was not impossible.

The moral of this outbreak has no doubt already been drawn by the hospital authorities themselves; it is unwise for laboratory cleaners to handle the food and utensils common to the mess unless they have first washed their hands, and for this, it seems, there were "no adequate arrangements."

No Death from Scarlet Fever

The week ending Sept. 21st, 1935, should not pass without comment for it was the first in the Registrar-General's records to show no death from scarlet fever registered in the great town aggregate or which the weekly reports are compiled. It is instructive to compare the number of deaths recorded

in the great town aggregate for the three September weeks in the four decades of the present century,

Weekly Scarlet Fever Deaths

September	1905	1915	1925	1935
First week	32	17	5	2
Second week	39	14	3	2
Third week	40	18	9	0

and the fall in the totals is the more remarkable when it is remembered that the number of towns comprising the aggregate has increased from 76 in 1905 to 121 in 1935.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 21ST, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2316; diphtheria, 1224; enteric fever, 73; acute pneumonia (primary or influenzal), 436; puerperal fever, 42; puerperal pyrexia, 126; cerebro-spinal fever, 17; acute poliomyelitis, 30; acute polio-encephalitis, 7; encephalitis lethargica, 6; typhus fever, 1 (Port of London), dysentery, 12; ophthalmia neonatorum, 76. No case of cholera or plague was notified during the week.

The number of cases in the infectious hospitals of the London County Council on Sept. 27th was 2679, which included: Scarlet fever, 876; diphtheria, 985; measles, 26; whooping-cough, 349; puerperal fever, 25 mothers (plus 8 babies); encephalitis lethargica, 270; poliomyelitis, 16. At St. Margaret's Hospital there were 14 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox or scarlet fever, 2 (1) from enteric fever, 5 (0) from measles, 16 (4) from whooping-cough, 22 (6) from diphtheria, 61 (9) from diarrhoea and enteritis under two years, and 19 (1) from influenza. The figures in parentheses are those for London itself.

It must be a long time since a week has gone by without the notification of a single death from scarlet fever. Deaths from diarrhoea and enteritis were distributed over 25 great towns, the highest being Liverpool 12, Nottingham 5, Gateshead 4, Hull, Manchester, and West Hartlepool each 3, no other great town more than 2.

The number of stillbirths notified during the week was 268 (corresponding to a rate of 42 per 1000 total births), including 38 in London.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The following all-day courses will take place during October: cardiology, at the National Hospital for Diseases of the Heart (Oct. 7th to 18th); medicine and surgery and the specialities at the Metropolitan Hospital (Oct. 7th to 18th); gynaecology, at the Chelsea Hospital for Women (Oct. 21st to Nov. 2nd); neurology, at the West End Hospital for Nervous Diseases (Oct. 21st to 26th); chest diseases, at Victoria Park Hospital (Oct. 28th to Nov. 2nd). Week-end courses will be held in heart and lung diseases at the Royal Chest Hospital (Oct. 12th and 13th); obstetrics at the City of London Maternity Hospital (Oct. 19th and 20th); physical medicine, at the St. John Clinic and Institute of Physical Medicine (Oct. 26th and 27th). Lectures on endocrinology will be given at the National Temperance Hospital, on Tuesdays and Thursdays at 8.30 P.M., from Oct. 8th to 24th; on modern gynaecology at the Medical Society of London, at 4 P.M. on Thursdays, from Oct. 10th to Nov. 7th; and on anatomy and physiology for the Primary F.R.C.S. at the Infants Hospital on Mondays, Wednesdays, and Fridays, at 8.30 P.M., from Oct. 7th to Nov. 29th. Courses arranged by the fellowship are open only to members. Further particulars may be had from the secretary of the Fellowship, 1, Wimpole-street, London, W.1.

MEDICAL NEWS

HOSPITAL DINNERS

St. Mary's Hospital

Mr. Duncan Fitzwilliams took the chair at the dinner at Claridge's last Saturday and found himself the toast of the evening. Dr. C. M. Wilson pointed out that when the tyro was apt on such occasions to make his subject sound indistinguishable from Lord Lister the expert proposer of toasts was recognisable by his ability to find chinks in the victim's armour. Mr. Fitzwilliams, however, must receive admiration for his courage in one thing at least—that he had been able to give up golf when he found he could not play it. His recreations were stated to be shooting and fishing, but what he really liked was playing at soldiers. We must enjoy this Elizabethan while we could; for already the tom-toms were beating in the bush and Dr. Wilson had a feeling that the streets of Addis Ababa would soon be seeing Fitzwilliams' car. He was a big man, immune from smallness, and his example showed how immeasurably a community gained by the presence of a personality. Replying, Mr. Fitzwilliams described Dr. Wilson as the local Musolini, and said that if he had belonged to the League of Nations he would have offered parts of his colleagues in exchange for himself as chairman. Referring to exhibits in the lobby he reported that the hospital had won the inter-hospital rugby (and A cup), the cricket (and A cup), and many other trophies. It had lost the association football cup by one goal and the hockey cup to the winners; and it possessed in Lovelock probably the finest runner that this country had seen for generations. After speaking of the death of Prof. Collingwood, whose place has been taken by Prof. A. St. G. Huggott, he referred to the resignation of Dr. Wilfred Harris and Sir William Wilcox. Dr. W. D. W. Brooks and Dr. D. H. Brinton had been appointed to the medical staff, and Mr. Fitzwilliams was able to illustrate their qualifications by quoting stories they had told him. He announced also that the staff had been so very prosperous of late that west-end consulting rooms could no longer contain their patients; but fortunately an anonymous donor had been persuaded to provide paying accommodation at the hospital. All this information was generously interlarded with irrelevancies, and the company dispersed in high good humour.

Middlesex Hospital

At the Savoy Hotel on Tuesday last an efficient installation of microphones made every speaker clearly audible to all the 363 diners. Dr. Campbell Thomson expressed his satisfaction at presiding in a year when the Middlesex Hospital celebrated its centenary and completed its rebuilding. In reviewing its new features, he spoke especially of the clinical unit, provided by Mr. S. A. Courtauld, where hospital and school can collaborate in the study of obscure diseases, and the X ray therapy and diagnosis departments, given and endowed by Mr. Meyerstein and Mr. Collins respectively. Mr. Meyerstein, one of the hospital's greatest benefactors, had that evening sent him a telegram offering £3000 to endow a second scholarship for University of London students. The medical school, said Dr. Thomson, had become a fitting partner for the splendid new hospital, and he mentioned that a ward had now been named after Mr. Webb-Johnson, treasurer of the school—a compliment never before paid to a member of the active staff. Mr. Courtauld and Dr. Boldero replied to the chairman's toast of the Hospital and School. Dr. Boldero, as dean, said that students of to-day behaved a great deal better than their predecessors: only two chairs had so far been broken in the new clinical theatre—one by a large visitor from America and one by a member of the Royal Family. They also showed much activity in the more important games: thus, four and often five rugby teams turned out on Saturdays, and the cricket team had not been beaten till the final. Dr. M. Hynes, as Broderip scholar, said that the teaching in preliminary sciences at Middlesex was the envy and admiration of students who came from places where these subjects were considered as

ends in themselves rather than as the foundation of medicine. Mr. E. W. Richey wittily proposed The Guests, and Mr. H. L. Eason, vice-chancellor of London University, replied. For forty years, he said, there had been nothing approaching the developments carried through at the Middlesex Hospital during the last twelve years. He hoped the voluntary hospital system, with its freedom of action and scope for heterodoxy, would never die, but he saw risks in cooperation with such bodies as the London Council. ("I'm all in favour of cooperation," said the elephant, as it sat down on the pleasant's eggs with the laudable intention of keeping them warm.) What was really essential, however, was to keep the freedom and individuality of the teaching schools, and the public should learn that the teaching hospitals were those which must at all costs be supported.

In proposing the chairman's health, Mr. Webb-Johnson was in most amusing vein; but his tribute to Dr. Campbell Thomson was none the less impressive. No dean, he said, had ever entered so closely into the students' activities, and his service to the school before and during the late war was made possible only by surrender of all personal ambition in favour of the Middlesex Hospital and its greater good.

Westminster Hospital

Old students of Westminster Hospital medical school turned up in large numbers to their annual dinner on Sept. 28th, stimulated no doubt by interest in the plans for rebuilding hospital and school. Dr. Vivian Orr presided at the dinner, which was held at the Trocadero restaurant. Mr. E. Rock Carling, who proposed the toast of Hospital and Medical School, said they were at a critical period, with the centenary just over and the rebuilding ahead. Of the two classes of his hearers one would be glad to know that at the new hospital there would be a gymnasium and two squash courts; the other that the pathological department was to be adequate. He was glad to assure both that they were within reasonable sight of obtaining the money necessary for the new buildings. Dr. Arthur Davies, in responding, remarked that Westminster students always remained students, and that "Broadway," the hospital magazine, was an important link between old and new. Mr. J. O. Collin, secretary of the Students Clubs Union, responded on behalf of the school. Dr. Adolphe Abrahams, dean of the medical school, then proposed The Guests, with what he described as the correct proportion of eulogy and malice, although in regard to one guest he was fain to admit that he was really as nice as he looked. Sir James Hartigan, director-general, A.M.S., acknowledging the toast, said that the R.A.M.C. College would welcome the Westminster as near neighbour. He spoke of the need for strengthening the medical branches of the defence forces and of the confidence with which he would look to the Westminster school for support. Mr. W. R. Halliday, LL.D., principal of King's College, who also replied, gave an entertaining account of his practice as an unqualified doctor on an Aegean island during the late war, and went on to express anxiety at the overcrowding of the medical curriculum with specialties. The reports of sundry committees did not, he felt, go far enough in simplifying the curriculum. He was old-fashioned enough to believe that one had to learn in the preliminary stage the basic things and go on to other things afterwards if one had the time. Speaking of the relation between King's as a pre-medical and Westminster as a clinical school, he was not discouraged by the lapse of the legal connexion, feeling as he did that voluntary association was better. Finally, he regretted the forthcoming departure of Prof. D. M. Blair whose alma mater had claimed him. Mr. Arthur Evans, senior surgeon, proposed "The Chairman," which led to a graceful exchange of hospital lore.

Mr. Leslie Paton has been elected an honorary member of the Société belge d'Ophthalmologie.

University of London

Three lectures on the history of medicine will be delivered at University College hospital medical school by Prof. Charles Singer on Oct. 8th, 15th, and 22nd, at 5 P.M. The lectures are open to all medical students of the University.

University of Leeds

At recent examinations the following candidates were successful:—

M.D.

J. Fielding, G. D. Gordon, J. M. Holmes, J. Q. Mountain, and S. Silverman.

M.B., CH.B.

Part I.—Lily Black, Marie H. Calverley, C. L. Davidson, M. Glick, R. C. Lawrence, W. Maude, E. Moore, J. P. Senior, I. Smith, and P. H. Wyon.

Part II.—A. J. E. Barlow, E. Brown, T. K. Cooke, S. C. Crystal, C. V. Light, D. G. Liversedge, T. W. Percival, F. A. Shackleton, R. G. Smithson, Helene E. Sykes, and E. Vining.

Part III.—R. G. Smithson (with Second Class Honours), A. J. E. Barlow, E. Brown, T. K. Cooke, S. C. Crystal, C. V. Light, D. G. Liversedge, T. W. Percival, F. A. Shackleton, Helene E. Sykes, and E. Vining.

B.CH.D.

J. Mort, H. D. Whiteley, and T. J. Wood.

L.D.S.

J. E. Barthel, O. F. Brown, J. E. Hitchen, Lilla E. Rider, and Dorothy E. Smithson.

D.P.H.

Kathleen S. Bruce, C. G. Eastwood, E. R. Hargreaves, Lois J. Ogilvie, J. F. Warin, and Lydia A. Wilson.

The William Hey gold medal and the West Riding panel practitioners prize in medicine have been awarded to Edwin Howard Kitching.

University of Bristol

On Tuesday, Oct. 22nd, at 5.15 P.M., Dr. Macdonald Critchley will deliver the Long Fox lecture in the physiological theatre of this University. He will speak on the occurrence of pain.

University of Birmingham

A short post-graduate course will be held in connexion with the opening of the winter session on Oct. 11th and 12th. At 5 P.M. on Oct. 11th Sir Walter Langdon-Brown will present the prizes and give an address to the students in the medical theatre of the University. A reception by the dean and a dinner will be held at the Grand Hotel that evening at 7.45 P.M.

University of Aberdeen

Dr. Ernest Cruickshank, professor of physiology in Dalhousie University, Halifax, Nova Scotia, has been appointed regius professor of physiology in the University in succession to the late Prof. J. J. R. Macleod.

Ernest William Henderson Cruickshank was born in Edinburgh in 1888, and educated at Aberdeen, at Gordon's College, and later at the university whence he graduated M.B. in 1910. After holding the post of house physician at the Royal Infirmary he went to University College, London, with a Carnegie research fellowship, and remained there until 1915 when he served as a temporary captain in the R.A.M.C. with the 9th Scottish Division and 41st Battalion of the Machine Gun Corps. In 1919 he was appointed officer-in-charge of the Prisoners of War Repatriation Commission to the 3rd Bavarian Army Corps Area. In the same year he returned to take the higher degrees of D.Sc. Lond. and M.D. Aberd. His appointment to the post of instructor of physiology at the Washington School of Medicine, St. Louis, took him to America in 1920, and the next four years of physiology at the Peking University. He returned to America for two years travelling fellowship. In 1926 he took the Ph.D. Camb. and became M.R.C.P. Lond. He went to India as professor of physiology and biochemistry at the Prince of Wales Medical College, at Patna, and for a time he was also Sukhr Raj Ray reader in natural science at the University of Patna. In 1928, the year in which he took up his present chair, he published a book entitled the "Value of Scientific Thought in the Advancement of Modern Medicine." Prof. Cruickshank has also written text books on physiology and contributed many articles to the Society of

Infectious Diseases Hospital for North-East Lancashire

At a conference held at Accrington, which was attended by various representatives from neighbouring boroughs, it was decided that the erection of an infectious diseases hospital for North-East Lancashire was desirable. The annual cost of maintenance was estimated at about £8000 and the cost of building at between £600 and £800 per bed. It is proposed that there should be about 20 beds.

Post-Graduate Course at Leeds

A series of weekly lecture-demonstrations will be held at the General Infirmary on Tuesdays at 3.30 P.M. from Oct. 8th to Dec. 17th. Further particulars may be had from the honorary secretary of the post-graduate committee, the General Infirmary, Leeds.

Royal Free Hospital

A short post-graduate course for former students will be held at this hospital on Nov. 29th and 30th and Dec. 1st. Further particulars may be had from the secretary of the London School of Medicine for Women, Hunter-street, W.C.1.

Tuberculosis Clinic for East Ham

Mr. Arthur Greenwood recently opened a new clinic for the treatment of tuberculosis in the grounds of Durban House, Katherine-road, East Ham. The clinic has cost about £6000, and provides up-to-date facilities for treatment. It is erected on a site which it is hoped will become the public health centre of East Ham.

National Radium Commission

The new commission has been elected and consists of the following members: Lord Donoughmore (Chairman), *Sir Cuthbert Wallace, P.R.C.S. (Vice-Chairman), Dr. Thomas Carnwath (appointed by the Minister of Health), Dr. Thomas Ferguson (appointed by the Secretary of State for Scotland), *Dr. Rupert Hallam, Mr. G. W. C. Kaye, D.Sc. (Joint Hon. Secretary, appointed by the Department of Scientific and Industrial Research), Prof. J. C. G. Ledingham, F.R.S. (appointed by the Medical Research Council), *Mr. J. J. M. Shaw, F.R.C.S., *Mr. G. F. Stebbing, F.R.C.S. (Joint Hon. Secretary), *Prof. Beckwith Whitehouse, F.R.C.S., and *Prof. James Young, F.C.O.G. (*Appointed by The National Radium Trust.)

Association of Industrial Medical Officers

As a result of many months' negotiations, this Association came into being at a meeting at the London School of Hygiene on Sept. 27th, when 20 medical practitioners giving whole-time services to industrial firms in London and elsewhere decided to form it as the Association representative of their branch of practice. Their number will be augmented at an early date by the election to membership of many other whole- and part-time practitioners actively employed by industrial firms, all of whom are invited to apply for membership. The Association replaces, and continues the work of, the previous Council of Industrial Medicine which was formed ten years ago in the Federation of Medical and Allied Services. Its members continue also to constitute the advisory medical committee of the Industrial Welfare Society. The new Association will hold its meetings at the London School of Hygiene. There will be three each year in London and one in the provinces, and each meeting will be followed by a dinner in the School and a conference on the following day. The first chairman is Dr. N. Howard Mummery, of J. Lyons and Co., Ltd., and the hon. secretary is Dr. Donald Stewart, of Imperial Chemical Industries, Ltd., Birmingham. The objects of the Association are to provide the means whereby medical practitioners attached to industrial concerns can meet to discuss the many problems they meet with in their work, both in regard to preventive medicine and remedial surgery, and thus enhance their value to the management of their individual firms, promote the knowledge of their specialty, and increase their usefulness to industry as a whole. Although a good deal has already been done in these directions during recent years, it has been obvious that a more intensive study directed to reducing the vast amount of unnecessary industrial incapacity, and absenteeism, is needed. This the new Association has the means and the will to carry out. Already a good start has been made, for the first conference held on Sept. 28th a paper was read by Dr. Leonard Lockhart, of Messrs. Boots, Ltd., on the present position and future of industrial medicine, when a lively debate followed and particular attention was given to the relations of the members to private and panel practitioners and to hospitals and clinics in promoting the recovery of sick or injured employees.

Aberdeen New Maternity Hospital

The King has sent a donation of £30 to the building fund of the new maternity hospital at Aberdeen. The money was part of the proceeds for admission to Balmoral Castle grounds during the summer.

Cumberland Infirmary

The committee of management of this hospital have presented to the governors a scheme for the extension of the institution which allows for the erection of two new surgical wards, a new children's ward, a skeleton fourth ward, and a new operating theatre. Each of the new wards will accommodate 20 beds. A sum of £22,240 has been subscribed or promised for the extensions.

Grocers' Company Scholarships

An election for three of the scholarships which the Grocers' Company offers with the object of encouraging original medical research will take place in May, 1936. Each scholarship is worth £300 per annum, and an allowance is given for apparatus and other expenses in connexion with the work. The scholarships are tenable for one year but are renewable for a second or third year. Applications must be sent before the end of April to the clerk, Grocers' Hall, London, E.C.2.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES**ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.**

TUESDAY, Oct. 8th.

Therapeutics and Pharmacology. 5 P.M. Dr. Dorothy C. Hare: Therapeutic Observations on Non-specific Colitis. (Pre-identical address.)

Psychiatry. 8.30 P.M.

Dr. H. J. Norman: Psychiatric Digressions. (Pre-identical address.)

FRIDAY.

Clinical. 5.30 P.M. (Cases at 4.30 P.M.) Cases: Mr. W. R. R. Monteith: 1. Bony Tumour of the Pelvis. Dr. F. Parkes Weber and Dr. A. Schlüter: 2. Local Fat-hyperplasia from repeated insulin injections. 3. Riedel's Lobe and Hepatoptosis. 4. Sequel to Removal of a Lymph-gland. 5. Spondylosis in a Young Man. Dr. Gerald illustrating Aurotherapy. Dr. C. anatoporphyrinuria and Hydroa Aestivale. Dr. Terence East: 11. Heart-block with Mitral Stenosis.

Ophthalmology. 8.30 P.M. (Cases at 8 P.M.) Mr. Cole Marshall: The Bipolar Electrolytic Treatment of Detachment of the Retina. Wing Commander P. C. Livingston: Modern Life and Binocular Vision.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, Oct. 8th.—9 P.M. (Great Western Royal Hotel, W.). Dr. A. K. Gibson: Organisation of Medical Practice.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY.

THURSDAY, Oct. 10th.—8.45 P.M. (11, Chandos-street, W.). Dr. C. M. Bevan-Brown: Psychological Schools, a plea for correlation.

BIOCHEMICAL SOCIETY.

THURSDAY, Oct. 10th.—2.30 P.M. (Biochemical Laboratory, Cambridge). Short Communications.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, Oct. 8th.—1 P.M. (11, Chandos-street, W.). Dr. Gerald Slet: Medical-legal Aspects of Drunkenness.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.

THURSDAY, Oct. 10th.—3.30 P.M. Sir Walter Langdon-Brown: Modern Aspects of Endocrinology.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.**ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.**

THURSDAY, Oct. 10th.—5.30 P.M. Dr. W. B. Coley: Treatment of Inoperable Malignant Tumours with the Toxin of *Proteus* and *Bacillus prodigiosus*, based on a study of developments from 1892 to 1934.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 7th. to SATURDAY, Oct. 13th.—NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westminster. Dr. A. A. Bailey course in cardiology. METROPOLITAN HOSPITAL, Kensington Road, E. All day course in medicine, starting at 10 o'clock. NATIONAL TUBERCULOSIS HOSPITAL, Harpenden Road, N.W. Tuesday, Oct. 8th. Dr. Leys: Surgery of Primary

and testis. THURS., 8.30 P.M., Dr. Donald Hunter: Parathyroid.—MEDICAL SOCIETY OF LONDON, Chandos-street, W. THURS., 4 P.M., Dr. V. B. Green-Armistage: Practical non-operative gynaecology.—ROYAL CHEST HOSPITAL, City-road, E.C. Week-end course in diseases of the heart and lungs.—Open only to members of the fellowship.

UNIVERSITY COLLEGE HOSPITAL, W.C.

THURSDAY, Oct. 10th.—10 A.M., Dr. W. N. Goldsmith: Acneiform Eruptions. 11 A.M., Mr. C. W. Flemming: Osteo-arthritis of the Hip-joint. 11.30 A.M., Miss Freda Kelly: Minnitt's Machine for Gas-air Analgesia in Labour. Noon, Prof. F. J. Browne: Placenta Previa. 2 P.M., Sir Thomas Lewis: Symptoms of Gross Arterial Disease of the Limbs. 2 P.M., Dr. W. J. Pearson: Pulmonary Tuberculosis in Infants. 3 P.M., Dr. R. W. A. Salmond: The Diagnosis of Gastric, Duodenal and Appendix Lesions by X Rays. 4 P.M., Dr. F. M. R. Walshe: Poliomyelitis.

FRIDAY.—10 A.M., Dr. H. P. Himsforth: The Significance of Glycosuria. 11 A.M., Mr. Gwynne Williams: The Surgical Treatment of Arterial Disease in the Limbs. Noon, Dr. Kenneth Harris: Heart Attacks. 2 P.M., Mr. A. J. Gardham: Follow-up Cases Treated by Radium. 2 P.M., Dr. H. N. Webber: Closed Circuit Method of giving Gas and Oxygen. 2 P.M., Dr. E. A. Blake Pritchard and Dr. L. P. E. Laurent: Cases of Myasthenia Gravis under Treatment with Prostigmin 3 P.M., Dr. D'Arcy Hart: Lipiodol Injection for the Diagnosis of Bronchiectasis. 3 P.M., Mr. Julian Taylor: Obstruction of the Common Bile-duct. (Open only to former students of the hospital.)

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 10th.—2 P.M., Dr. Brain: Principles of Treatment of Skin Diseases in Children. 3 P.M., Dr. Payne: Diabetes in Children (Part I.).

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

KING'S COLLEGE HOSPITAL, Denmark-hill, S.E.

THURSDAY, Oct. 10th.—9 P.M., Dr. Wilfrid Sheldon: Tuberculosis in Children.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Oct. 11th.—4 P.M., Mr. A. Brown Kelly: Oesophagus in Young Children: some anatomical and clinical observations (annual address).

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Oct. 7th.—3.30 P.M., Dr. Kinnier Wilson: Aphasia Apraxia.

TUESDAY, 3.30 P.M., Dr. Purdon Martin: The Cranial Nerves (I.).

WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.

THURSDAY.—3.30 P.M., Dr. Riddoch: The Sensory System (I.).

FRIDAY.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (I.).

Out-patient clinic daily at 2 P.M.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

TUESDAY, Oct. 8th.—5 P.M., Dr. M. Sydner Thomson: Animal Diseases Communicable to Man.

WEDNESDAY.—5 P.M., Dr. I. Muende: Introduction to Histopathology of the Skin.

Thursday.—5 P.M., Dr. J. M. H. MacLeod: Ringworm Infections.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, Oct. 7th.—10.30 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Gynaecological and Surgical Wards, Eye and Gynaecological Clinics.

TUESDAY.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Throat Clinic.

WEDNESDAY.—10.30 A.M., Children's Wards and Clinic. Medical Wards. 2 P.M., Eye Clinic, Gynaecological Operations. 4.15 P.M., Mr. Harvey Jackson: Surgical Methods in Localization of Brain Tumours.

THURSDAY.—10 A.M., Neurological and Gynaecological Clinics. Noon, Fracture Clinic. 2 P.M., Eye and Genito-urinary Clinics.

FRIDAY.—10 A.M., Skin and Dental Clinics. Noon, Lecture on Treatment. 2 P.M., Throat Clinic. 4.15 P.M., Dr. Kon-tam: Cardiac Pain.

SATURDAY.—10 A.M., Children's and Surgical Clinics. Medical Wards.

The lectures at 4.15 P.M. are open to all Medical Practitioners without fee. Operations and medical and surgical clinics daily at 2 P.M.

UNIVERSITY OF LONDON.

TUESDAY, Oct. 8th.—5 P.M. (University College Hospital Medical School), Prof. Charles Singer: Some Medical Books of Historical and Artistic Interest.

PUBLIC DISPENSARY AND HOSPITAL, Leeds.

WEDNESDAY, Oct. 23rd.—4 P.M., Mr. L. N. Pymh: Septic Infections of the Hand.

GENERAL INFIRMARY, Leeds.

TUESDAY, Oct. 8th.—3.30 P.M., Dr. Watson: Cases exhibiting variation in blood pressure.

ROYAL INFIRMARY, Manchester.

TUESDAY, Oct. 8th.—4.15 P.M., Dr. D. Dougal: Dysfunctional Uterine Haemorrhage.

FRIDAY.—4.15 P.M., Dr. F. E. Tyboste: Demonstration of Medical Cases.

Appointments

ALLAN, S. M., M.D. Glasg., D.P.M., has been appointed First Senior Assistant Medical Officer at the Mental Hospital, Whittingham.

BONNELL, H. E., B.Sc. Wales, M.R.C.S. Eng., part-time Pathologist to the East Ham Memorial Hospital.

FLEMING, J. A. C., M.B., F.R.C.S. Edin., D.R., Assistant Radiologist to the Cancer Hospital (Free), London.

FLOOD, P. A., M.R.C.S. Eng., D.M.R., Assistant Radiologist to the Cancer Hospital (Free), London.

GILMOUR, MARY D., M.B. Glasg., Pathologist at the Marie Curie Hospital, London.

TURNER, M.D. Lond., D.P.H., Senior Medical Officer (Education) for Leicester.

Certifying Surgeon under the Factory and Workshop Acts: Dr. B. J. SIM (Wigston District, Leicester).

Vacancies

For further information refer to the advertisement columns

Ashdon-under-Lyne, District Infirmary.—Two H.S.'s. At rate of £150.

Aylesbury, Royal Buckinghamshire Hospital.—Second Res. M.O. At rate of £150.

Beckenham, Bethlem Hospital, Monk's Orchard.—Res. H.P. At rate of £150.

Belgrave, Hospital for Children, Clapham-road, S.W.—Two H.P.'s. and H.S. Each at rate of £100. Also Hon. Radiologist.

Birmingham General Hospital.—Med. Reg. and Res. M.O. £155.

Blackburn, Queen's Park Hospital and Institution.—Res. Jun. Asst. M.O. £150-£200.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Buxton Clinic for Rheumatism and Allied Diseases.—H.P. At rate of £150.

Cambridge, Addenbrooke's Hospital.—H.P. At rate of £130.

Cambridgeshire C.C.—Asst. County M.O. £600.

Cancer Hospital, Fulham-road, S.W.—Surgical Registrar.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Third Res. H.S. At rate of £75.

Central Middlesex County Hospital.—Med. Supt. £1300.

Chailly, Commu.—E.—Cas. O. At rate of £100.

Douglas, Infirmary.—Second H.S. £150.

East Ham County Borough.—Asst. M.O.H. £500.

Exeter, Royal Devon and Exeter Hospital.—H.S. At rate of £150.

Folkestone, Royal Victoria Hospital.—Hon. Asst. Ophth. Surgeon.

Goldie Leigh Hospital, Abbey Wood, S.E.—Consulting Physician. £150.

Great Yarmouth General Hospital.—H.S. £140.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Hove General Hospital.—Res. M.O. At rate of £150.

Infants Hospital, Westminster.—H.P. At rate of £75. At hospital.—Res. Surg. Officer. £400.

Ipswich, Mental Hospital.—H.P. At rate of £150.

Ipsworth, West Middlesex County Hospital.—Asst. M.O.'s. Each £400.

Jersey General Hospital and Poor Law Infirmary.—Asst. Res. M.O. At rate of £150.

Kidderminster and District General Hospital.—H.S. £150.

Kingston-upon-Hull City and County.—Asst. M.O.H. £300.

Lambeth Hospital, Brook-street, S.E.—Pathologist. £1100-£50-£1300.

Lancaster, County Mental Hospital.—Temp. Asst. M.O. 7 guineas per week.

Leeds City.—Asst. Clin. Tuberc. O. £500.

Leeds, Asst. M.O.'s. Each £500.

Asst. M.O.'s. £250.

Hospital.—Res. H.P. At rate of £150.

London Hospital Medical College, E.—Hutchinson Triennial Prize, 1938.

London Lock Hospital, 253, Harrow-road, W.—Surg. Reg. £100.

Infirmary.—Sen. H.S. £180.

Hospital and Institution.—Jun. Asst. £200.

Manchester, Mosaic Hospital for Infectious Diseases.—Jun. Res. Asst. M.O. At rate of £250.

Manchester Royal Children's Hospital, Pendlebury.—Res. Surg. O. At rate of £125.

National Temperance Hospital, Hampstead-road, N.W.—H.P. At rate of £100.

Newport, Mon., Royal Gwent Hospital.—Jun. Res. M.O. At rate of £135.

Northampton General Hospital.—H.S. to Ear, Nose, and Throat Dept. At rate of £150.

North-Western Hospital, Laven-road, Hampstead, N.W.—Pathologist. £1100-£50-£1300.

Norwich, Norfolk and Norwich Hospital.—H.S. to Spec. Depts. Also Cas. O. Each at rate of £120.

Nottingham General Hospital.—H.S. for Ear, Nose, and Throat Dept. At rate of £150.

Plymouth Mental Hospital, Blackdon, Ivybridge.—Asst. M.O. £350.

Plymouth, Prince of Wales's Hospital, Greenbank-road.—Res. Anaesthetist and H.S. to Spec. Depts. At rate of £120.

Road, E.—Asst. Physician. At rate of £100.

—H.P. At rate of £175.

Res. M.O. £250.

Great Portland-st., W.—

Two Registrars. Each £105.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. At rate of £100.

St. Bartholomew's Hospital, E.C.—Asst. Neurologist.

St. John's Hospital, Lewisham, S.E.—Res. H.P., Res. H.S. Also Res. Cas. O. Each at rate of £100.

St. Margaret's Hospital, Leighton-road, Kentish Town, N.W.—Visiting M.O. £200.

Salisbury, General Infirmary.—Res. M.O. £250.

Salop County Council.—Asst. M.O. £500.

Shrewsbury Royal Salop.—Surg. O. £250.

Also Res. H.S. and e of £160.

Southend-on-Sea General Physician and Surgeon.

South London Hospital for Women, Clapham Common, S.W.—Asst. Radiologist. £200. Also Med. Reg. £50.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.P. At rate of £150.

Stoke-on-Trent, Stanfield Sanatorium.—Res. M.O. £250.

Sunderland Children's Hospital.—H.P. £120.

Surrey County Council.—Jun. Asst. M.O. for County Sanatorium. At rate of £250.

Sutton, Surrey, Downs Hospital for Children.—Asst. M.O. £250.

Swanley, Home, Parkwood.—Res. M.O. £200.

Tilbury, Victoria.—Sen. as. Sorting O. At rate of £200.

West End, Diseases, 73, Welbeck-street, W.—Hon. Chm. Psychologist.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. Res. H.S.'s. At rate of £150 and £100 respectively.

Westminster Hospital Annex, 66, Fitzjohn's-avenue, Hampstead. Res. M.O. £200.

Weston-super-Mare, P. £150.

Willesden General N.W.—Physio-n. e of £100.

Yose, and Throat

York Dispensary.—Res. M.O. £175.

Yorkshire Children's Orthopaedic Hospital, Kirbymoorside.—H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Rhondda (Treorchy) (Glamorgau), Abercider (Banff), and Leiston (Suffolk).

Births, Marriages, and Deaths

BIRTHS

BOGGM.—On Sept. 26th, at Welbeck-street, the wife of R. H. Boggm, M.S. Lond., of a son.

CRAWFORD.—On Sept. 17th, at Southsea, the wife of Surg. Lt.-Comdr. T. G. B. Crawford, R.N., of a daughter.

DARMADY.—On Sept. 28th, at Devonshire-place, W.1, the wife of E. M. Darmady, M.R.C.S. Eng., of a daughter.

EVANS.—On Sept. 24th, at Devonshire-place, W.1, the wife of Horace Evans, M.D. Lond., of a daughter.

GREEN.—On Sept. 20th, at Sevenoaks, the wife of Ralph Green, M.R.C.S. Eng., of Borough Green, Kent, of a son.

HARRIS.—On Sept. 22nd, at Chelmsford, the wife of H. A. H. Harris, F.R.C.S. Edin., of a daughter.

LEHMANN.—On Sept. 24th, at Wickham Market, Suffolk, the wife of Harold Paul Lehmann, M.R.C.S. Eng., of a son.

LLOYD.—On Sept. 23rd, at Aldeburgh, the wife of W. Jeaffreson Lloyd, M.B. Camb., of a daughter.

MORRISON.—On Sept. 21st, at Llanelli, the wife of W. J. Morrison, M.B. Belf., of a son.

MARRIAGES

HARGREAVES—PURSER.—On Sept. 26th, quietly, at Hubberholme Church, Yorkshire, Edward Rhodes Hargreaves, M.B. Camb., D.P.H., to Hilda Nancy, only daughter of Colonel L. M. Purser, D.S.O., M.B.

DEATHS

ALLEN.—On Sept. 24th, at Baling, William Hamilton Allen, M.D. Dub., late of Stanmore, Middlesex, suddenly, at Harrogate, Surgeon-General Joseph Chambers, K.C.B., C.M.G., 70 years.

Wellington Villa, 1455, Ashton Old, L.R.C.P. Ed., & L.N., L.R.C.S. Ed.

L.R.F.P.S. Glas., 1887, Mem. B.M.A., late Res. Med. Off. Chorlton Union Hosps., Hon. Surgeon Chorlton-upon-Medlock Disp., son of the late Dr. and Mrs. Edwin Jones, of Rhyll.

LEE BORTON.—On Sept. 24th, R. Lee Bolton, L.R.C.P. Edin., of Feteham, Leatherhead, late of Leeds.

PEDLEY.—On Sept. 21st, at Peacehaven, Sussex, Samuel Edward Pedley, M.R.C.S., L.D.S. Eng., of Welbeck-street, W., in his 73rd year.

PHILLIPS.—On Sept. 21st, at Llandilo, David Phillips, M.R.C.S. Eng.

SHRUBSALL.—On Sept. 25th, suddenly, at Hampstead, Frank Charles Shruballs, M.D. Camb., F.R.C.P. Lond.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

THE ATTITUDE OF SURGERY TO
HÆMATEMESIS *

By G. GORDON-TAYLOR, O.B.E., M.A. Aberd.,
F.R.C.S. Eng., F.R.A.C.S. (Hon.)
SURGEON TO THE MIDDLESEX HOSPITAL

No clinical mishap is more dramatic and none is more productive of alarm to the patient and of consternation to the onlooker than is the vomiting of blood: nor perhaps has any clinical phenomenon a pathogeny so multifarious. The hæmatemesis due to peptic ulcer is that with which surgery is most frequently, though not exclusively, concerned, and from the effects of which timely operative interference alone can on occasion effect a rescue.

By way of a caveat it should be remembered that this address in no way purports to be a polemic against the non-operative treatment of hæmorrhage from a gastric or duodenal ulcer; overt hostility between medicine and surgery belongs to a bygone era; an appeal is merely being made for still closer co-operation between both branches of the profession in the treatment of these difficult and anxious cases.

Discrepancy of statistics.—Statistics concerning the relative frequency of the various pathological states associated causally with hæmatemesis appear to exhibit much diversity in different countries, and even in the experience of authors in the same realm or State; they can vary widely in different institutions in the same town; there seem also to be divergencies of opinion according as the figures are culled from the records of medical or surgical workers. Thus Pauchet¹ of Paris affirms that 90 per cent. of the cases of profuse hæmatemesis concern gastro-duodenal ulceration and that only 10 per cent. of the hæmorrhages are due to hepatic, splenic, or appendix disease; from the same city, however, emanate the findings of Gutman and Demole,² who, utilising the statistics of the Salpêtrière, found that gastric and duodenal ulcers are the cause of only 19 per cent. of the cases of hæmatemesis investigated.

While Delore³ of Lyons affirms that gastro-duodenal ulcer is responsible for half the cases of hæmatemesis, Finster⁴ of Vienna thinks that out of every 100 grave hæmorrhages from the stomach, in 98 the source is some large artery in the gastric or duodenal wall, and that in only 2 per cent. can the liver or spleen be incriminated.

Urgent Surgery

With the exception of ulcer-hæmorrhages there can scarcely be an occasion when urgent surgery may legitimately be discussed as a means of hæmostasis in gastric bleeding, and the would-be operator should think once again and make assurance doubly sure before deciding to interfere surgically during acute hæmatemesis from the stomach.

Whether surgery "à froid" is the appropriate measure for a particular case of hæmorrhage due to a gastric carcinoma can only be determined after radiological examination, and in most cases the possibility of removal—the sole measure of real value—can be settled only after laparotomy. Recently the employment of continuous slow blood transfusion⁵ in cases of gastric cancer where hæmorrhage dominates the clinical picture has been found

to arrest the bleeding and rapidly to combat the anæmia; and the surgeon has been enabled to explore the abdomen with the briefest delay.

The hæmorrhages of *splenic anæmia* are, unfortunately, not always permanently arrested by the removal of the spleen, and never necessitate urgent surgery; the operation, which may require considerable technical skill, demands also some forethought, perhaps preliminary radiation, and the employment of expert hæmatology, not excepting a minute enumeration of blood-platelets.

In diseases of the *gall-bladder or appendix*, and in cases of *essential thrombocytopenia* associated with bleeding from the stomach, surgery performed at the time of election may indeed play a useful and curative part; in respect of most of the other pathological states associated with hæmatemesis which are laboriously listed in students' manuals of medicine, constituting therein a challenge to the memory of the youthful and anon advertising the meritorious lucubrations of the "crammer," heedless resort to operation bespeaks the ignorant, the commercial, or the experimentalist, and will naturally be dismissed from further consideration by any surgeon of judgment.

Before any decision is taken on the matter of operating for, and in the presence of, a severe hæmatemesis, the greatest caution must be exercised to ensure absolute accuracy in the diagnosis of the causation of the hæmorrhage, for almost the only pathological state which justifies urgent surgery is that of *bleeding from a chronic ulcer*. There should preferably be clinical, radiological, even biochemical evidence of the existence of a chronic ulcer, or if the details of the patient's previous history are not available the anamnesis should leave in the observer's mind no doubt as to the existence of a chronic ulcer of stomach or duodenum, and no uncertainty as to this being the source of the cataclysmic menace to the patient's safety.

I had long taught that the *hæmorrhage of acute ulcer* never required surgery, and that bleeding from this source can be combated, save on the rarest occasions, by medical measures and by the transfusion of blood. Nevertheless, in several cases of this nature that I have encountered recently, non-operative measures, even the continuous blood-drip, did not succeed in arresting the hæmorrhage, and I was constrained to operate on desperately ill patients to save life. The continuous blood-drip,⁶ if it did not succeed in obviating the need for operation, yet proved to be a most valuable aid to surgery, and its employment before, during, and after the operation, contributed enormously to the success that rewarded the surgical intervention.

Apart from the reference to these few acute ulcers and to a unique case of thrombocytopenia with severe hæmatemesis where urgent operation was demanded and proved successful, it is the attitude of surgery to the *bleeding of chronic peptic ulcer* that forms the burden of this communication.

Surgical Prophylaxis of Hæmorrhage

Is surgery to be employed as a prophylactic measure against the hæmorrhage of gastro-duodenal ulceration?

An answer to this question would appear to depend upon (a) the incidence of hæmorrhage in connexion with ulcer, (b) the risk with which ulcer-hæmorrhage is fraught, and (c) the prospective mortality of any surgical measure contemplated.

* Address delivered to the Middlesex Medical Society, October 11, 1935.

(a) *The incidence of hæmorrhage.*—A history of hæmatemesis or of melæna or both was obtained by Hurst⁶ in 18 per cent. of cases of gastric ulcer and in 25 per cent. of the duodenal ulcers examined at New Lodge. The statistics of Lord Moynihan⁷ and of D. Balfour⁷ of the Mayo Clinic are similar; 20 per cent. of gastric ulcers and 25 per cent. of duodenal ulcers have bled.

Crohn and Manheim⁷ of the Mount Sinai Hospital, New York, found evidence of bleeding in nearly 30 per cent. of gastric ulcers, and in nearly 20 per cent. of duodenal ulcers admitted; they insist, however, that the percentage of ulcer cases gaining admission to the hospital is relatively small, and that probably only 10 per cent. of all ulcers bleed.

The cases admitted to New Lodge are necessarily of a more severe type, and Hurst's estimate of the percentage of ulcers that bleed is also about 10 per cent., which agrees with the figures of J. J. Conybeare⁷ computed from the statistics of Guy's Hospital.

(b) *What is the risk to life from ulcer hæmorrhages?*—Conybeare affirms that only 2·5 per cent. of patients with ulcers that bleed die of hæmorrhage; so that the risk of loss of life by bleeding from an ulcer is only about 1-in 400 or thereabouts. Alas! however, Ernest Bulmer⁸ of Birmingham found that in cases of hæmatemesis due to chronic peptic ulcer, treated by non-operative measures, there was a mortality of 11·6 per cent. The mortality of the Middlesex Hospital⁹ cases of hæmorrhage from chronic peptic ulcer treated medically amounted to 21 per cent., and an almost identical percentage was found by A. M. Cooke¹⁰ in 191 cases of gastroduodenal hæmorrhage admitted into St. Thomas's Hospital during seven years; 24·1 per cent. of these patients died.

R. S. Aitken,¹¹ dealing with the London Hospital figures for 1929-33, found an 11 per cent. death-rate; but in the cases classed as "severe" the mortality was no less than 42·8 per cent. F. F. Hellier,¹² dealing with the Leeds cases, records a 14·8 per cent. fatality. These are far higher figures than the comforting 2·5 per cent., and cannot be viewed complacently by those anxious to advance the therapy of ulcer-hæmorrhage. Nevertheless it seems certain that the chances of any patient with an ulcer dying of hæmorrhage cannot be worse than 1 in 40; the risk will vary with the length of the history and the chronicity of the ulcer. The decision in favour of surgery in peptic ulcer is not likely however to be determined on the question of prophylaxis against hæmorrhage. In the case of gastric ulcer, chronicity, the menace of malignancy, severity of pain, incapacity for work, &c., are more likely to be the deciding factors.

I have at this moment a bias in favour of an expectant attitude in the case of duodenal ulcer, regarding as indications for operation only stenosis, perforation, hæmorrhage, a large crater, duration of existence, and an incapacity for work. The only operation which is going to confer a permanent immunity from hæmorrhage is a resection or some type of exclusion, and in the case of a duodenal ulcer it would be difficult to press for an operation of this character purely as a prophylactic measure against bleeding.

(c) *The prospective mortality of an operation to prevent hæmorrhage* from a peptic ulcer will vary with the nature of the procedure envisaged, with the experience, skill, and judgment of the surgeon and with the general condition of the patient. In the most experienced and the most competent hands an operation of resection, or resection with exclusion,

carries nowadays a mortality of only about 3 per cent., but this represents the acme of surgical skill and experience. Yet this figure is greater than the risk run by the possessor of a peptic ulcer of dying of hæmorrhage; an operation undertaken solely on grounds of prophylaxis against bleeding is therefore to be discountenanced.

Previous History of Hæmorrhage

Does a history of hæmorrhage constitute an indication for surgery in chronic peptic ulcers?

The authoritative opinion of D. P. D. Wilkie¹³ favours medical treatment for the first hæmorrhage and in the event of a second bleeding it is recommended to wait for ten days after it has ceased and then to operate; it is admitted however that three patients have died during the second hæmatemesis. The mortality of cases of hæmatemesis from chronic ulcer of the stomach or duodenum treated medically at the Middlesex Hospital from 1924-33⁹ inclusive in which a second large hæmorrhage occurred was no less than 78 per cent., and with each successive bleeding the death-rate mounts higher. This seems to indicate the need of surgery before a second hæmatemesis occurs. Bulmer, too, holds the view that in the event of a hæmatemesis being followed by the presence of occult blood in the stools for some weeks, surgical interference should be utilised without delay; this opinion coincides with the view of Charles Bolton,¹⁴ based upon a wealth of experience which makes it of supreme value.

Probably in the near future interference before a second hæmorrhage may come to be regarded as the optimum time for surgery; on the other hand, it may be found just as difficult to persuade the resurected patient to submit to operation as to induce the physician to realise that second and subsequent hæmorrhages are increasingly fatal. Possibly, however, medicine will have triumphed over the peptic ulcer problem and will cure ulcer of the stomach and duodenum with a sureness and certainty approximating that with which it controls diabetes, pernicious anæmia, or some of the tropical infections; the necessity for decision as to the optimum time for surgery in hæmatemesis may then no longer arise.

Hæmorrhage from Chronic Ulcer

Does active hæmorrhage from a chronic peptic ulcer, whose existence is beyond cavil, require surgical treatment during the bleeding, or is surgery best practised after the bleeding has ceased?

It has been regarded by many, even by "interventionists," as more convenient and less harassing to operate after the first bleeding has ceased. This indeed may be a pious hope! How do we know that it will cease, or when it will cease? Surely the only rational attitude now is one of "armed expectancy."

1. In every case of hæmatemesis or melæna, whatever be the cause, immediate steps should be taken to organise donors from amongst the relatives and friends so that the certainty of a gallon of blood of the same or suitable group can be relied upon, should necessity arise. It is impossible to foretell what may happen in any case of hæmatemesis.

2. In every patient in whom the bleeding is more than slight—i.e., a pulse-rate of 100 or more and a hæmoglobin estimate of less than 80 per cent. in a man or 70 per cent. in a woman—a drip-transfusion should be commenced straightway.

3. It is desirable that every case of hæmatemesis should be transferred to an institution, and if there is a possibility of the case being one of hæmorrhage from a gastric or duodenal ulcer, the necessity for

fact that many were dealt with in institutions remote from personal supervision, and without all the arrangements necessary for adequate and repeated transfusion. A spirit of self-criticism and a disinclination to operate "à chaud" were thereby induced. Nevertheless, the total in groups (a) and (b) amounted to 32 cases, with 6 deaths—a 19 per cent. mortality-rate.

(c) A period of abstention from active surgery in these cases; this attitude coincided with the impetus given to the medicinal or alkaline treatment of ulcer, resulting from the papers of MacLean and the booming of this ancient method of therapy in the lay press. During this period, the mortality of acute hæmatemesis from chronic ulcer in cases which I saw in outlying hospitals and in private practice was enormous; there were no operations for active hæmatemesis at the Middlesex Hospital during this quinquennium. A few cases were, nevertheless, operated upon outside the hospital during this period, and a few successes rewarded surgical enterprise.

(d) Our therapeutic armamentarium for dealing with hæmatemesis has recently been reinforced by the introduction of the "continuous intravenous blood-drip" by Marriott and Kekwick.⁵ As a method of treatment it is fraught with great possibilities no less for the physician than for the surgeon. Experience with this method of giving blood has certainly brought me to operate with advantage upon cases which to their detriment might have been denied surgery; it has also slightly modified my views as to the time to operate on bleeding ulcers of the stomach and duodenum and even the type of hæmorrhage which requires surgery; it has certainly given me an increased, and increasing, confidence of bringing the undertaking to a successful issue.

Hæmatemesis, Perforation, and Complications

There is one group of cases to which a brief reference may be made.

(a) In a somewhat insignificant minority of ulcer-hæmorrhages there may be *concomitant perforation*. The association is fortunately rare, for there is much truth in the dictum of Moses Behrend,¹⁵ "perforated ulcers bleed rarely; bleeding ulcers perforate only very exceptionally." The two complications of a peptic ulcer may occur simultaneously in unmistakable fashion, and perforation will demand urgent operation; on the other hand, the twin nature of the catastrophe may be discovered only during the course of the operation. The association of an active hæmorrhage will naturally call for some modification of the technique habitually employed in dealing with perforation of a peptic ulcer.

I have actively intervened for this syndrome three times in connexion with gastric ulceration, and once for a bleeding and perforated duodenal ulcer; all four cases were dealt with by resection and all recovered. I have, however, dealt unsuccessfully with a perforated jejunal ulcer consequent upon a gastrectomy for duodenal ulcer; the jejunal ulcer was actively bleeding at the same time. In another case, after an exploration, I found it impossible to do anything for a patient with a bleeding gastro-jejunal ulcer, which still further complicated the clinical picture by eroding the transverse colon. In this last-mentioned case, with its ghastly communications, a bloody flux composed of diarrhoea and putrid melæna poured through the pathological anus into the stomach, whence it was rapidly ejected; the victim's sufferings were fortunately ended by death.

(b) Hæmorrhage from a peptic ulcer may *precede* perforation; the fatality of this sequence of complications is prodigious. In these cases the enfeebled condition of the patient from a hæmorrhage may mask the ordinary clinical picture of a perforation which may fail to be diagnosed.

(c) Finally, hæmorrhage may *complicate* the progress of a *successful operation for perforation*. In my own experience the results have been calamitous, whether the bleeding has been attacked by surgical reintervention or treated by medical measures. These hæmorrhages are usually ushered in by an increased pulse-rate and some elevation of temperature; they occur, as a rule, from 7 to 21 days after the initial emergency operation. The hæmorrhage may originate from the sutured ulcer itself, from some other ulcer in the stomach, or it may be a diffuse parenchymatous bleeding from the gastric wall. In two cases of my own, this last-mentioned condition of the gastric mucosa was found, and both these ended fatally.

Is there any prophylactic measure against this most lethal combination of catastrophe? Resection of stomach or duodenum can hardly be urged as a routine measure for perforated ulcer, though Alesandri¹⁶ and certain other continental surgeons speak well of it in early cases. In the hands of skilled and experienced surgeons it may be a sound measure, but an enormously increased mortality from perforated ulcer would result if this operation were regarded as the appropriate form of surgery in every case.

Post-operative hæmatemesis, due to the failure to occlude bleeding vessels in the stomach or intestinal wall, is all but unknown to me, since I rarely, if ever, employ clamps. *Indirect operations for peptic ulcer* of stomach or duodenum may lead to hæmorrhage from the original ulcer which is preferably dealt with by excision or exclusion. A fatal bleeding may take place from such a source, unless surgical reintervention is employed.

Hæmorrhage from anastomotic ulcers.—If these are complicated by severe hæmorrhage, the rules governing the treatment of peptic ulcers of stomach and duodenum should control the surgeon in this class of case. Amidst the anxieties of a complex artificial pathology, if urgent operation should be required or undertaken, the least possible should be done at the time; hæmostasis alone is to be secured.

Conclusion

It may still be long before physician and surgeon see absolutely eye to eye as to the necessity and as to the appropriate moment for operative interference; but I have no doubt whatever that ultimately the internist will become more alive to the menace of disaster which threatens the patient, and will become more surgically minded towards these cases than he may be at the moment. Until the arrival of the day when the department of medicine shall cure all ulcers, this valuable method of resuscitation should give the physician the same confidence in the power of surgery to deal successfully with hæmorrhage of an ulcer as with that of an ectopic gestation.

There is one danger that I foresee from continuous drip-transfusion: its very success in at least temporarily arresting hæmorrhage may lead to vexatious delay and to ill-judged postponement of obvious operation, until a time when the patient is worn out by the hope that is deferred, his tissues poisoned by morphia, his biochemistry altered by the starvation enjoined for the arrest of the bleeding, and his

cough-reflex abolished by hypnosis: by then all is ready for an impending low-grade pneumonia which will carry him off. When surgery is finally demanded as "un dernier ressort," is it little wonder that fatality ensues?

Increasing experience confirms the cherished conviction that the continuous blood-drip, aided by appropriate and timely surgery, is solving the ulcer-hæmorrhage problem and rationalising the treatment of these anxious cases, which have hitherto so frequently dismally disappointed the all-too-sanguine expectations of a futile and complacent inactivity; to this inert policy I was myself for a time idly, hopefully, disastrously partisan. Finsterer's "first forty-eight hours" is still the optimum period for surgical attack in hæmatemesis, and the golden age of gastric surgery will have been attained only when all cases of hæmorrhage from chronic ulcer come to operation within that space of time.

Let there be no procrastination, for delay is fraught with peril; early enterprise is the prelude to success.

AN OUTBREAK OF SCABIES IN A MENTAL HOSPITAL

By FRANK E. KINGSTON, M.B. Lond., D.P.M.

ASSISTANT MEDICAL OFFICER, WEST RIDING MENTAL HOSPITAL, WAKEFIELD

The problem of scabies in an institution has certain distinctive features. On the one hand, disinfection of all individual bedding and clothing is readily accomplished; the patients, moreover, are under constant observation and one can readily satisfy oneself that any treatment prescribed is carried out in detail. On the other hand, there is the wide range of dissemination from the undetected scabetic through accidental interchange of clothing and bedding, and the impracticability of treating all such possible contacts—as one can in the small family—as if they were actually infected.

In the mental hospital there are two further difficulties. The patients rarely complain of any discomfort and thus do not come forward for treatment; and, secondly, with a few exceptions, they do not coöperate. Not a few patients are actively hostile and resistive to any sort of attention; and the difficulty of applying any treatment which depends upon the opening-up of all burrows need not be stressed. Below is given briefly an account of an outbreak of scabies in the chronic female block of Wakefield Mental Hospital, comprising 12 wards and containing some 650 patients.

It may be mentioned here that the particular technique of sulphur ointment treatment followed was that recommended by Sequiera¹ of three rubbings with soft soap, three baths with thorough scrubbing,

and three liberal applications of unguentum sulphuris B.P. at intervals of 24 hours. The only detail omitted was the use of gloves and stockings after the application of the ointment. Clothing and bedding were autoclaved.

HISTORY OF THE OUTBREAK

The position at the end of April, 1934 (when I took over the charge of the block), was that of the dozen or so cases of scabies which had appeared in four separate wards since the beginning of the year, all had been energetically treated with sulphur-potash baths and sulphur ointment for periods of a week or more and were regarded as cured.

Early in May a patient was reported to have a rash, and examination showed well-advanced generalised scabies. Microscopical examination of a scraping revealed the sarcoptes. The patient was isolated in bed and the routine sulphur ointment treatment given. The following day the limbs of all the other patients in the ward were systematically examined. Two clinically certain and four doubtful cases were found. All six were isolated and treated. During the next few days all previously suspected or treated cases were thoroughly examined, and wherever a suspicious case was found the limbs of all other patients in the ward were examined without delay. All cases, whether certain scabies or only doubtful, were submitted to the routine treatment.

In this way some 30 cases were netted and isolated. Treatment was repeated at fortnightly intervals in all cases which appeared clinically to be still active and which showed, in addition, the sarcoptes or unhatched eggs in scrapings from the burrows. Isolation in bed was maintained for a week after all suspicious lesions had disappeared.

After about a month had elapsed it became apparent that while nearly all of the "doubtful" cases had cleared up hardly any of the clinically "certain" cases had done so, and not one of the cases in which microscopical evidence of the parasite had been found showed any permanent improvement; nor did stricter supervision of the treatment and the opening-up of all visible burrows with the scalpel give results commensurate with the time and energy expended.

The position in July can be summed up as follows: of ten cases in which the diagnosis had been confirmed microscopically not one had been cured by two courses of treatment. Five had been cured after 3, 3, 3, 4, and 5 courses respectively, while five remained active after 2, 2, 3, 3, and 5 courses respectively.

Treatment was now tried, tentatively at first, using a combination of sulphur and turpentine. The latter was chosen for the reason that it is capable of holding sulphur in solution and that it penetrates the skin.² It had the further recommendation that it is itself used as a parasiticide (for ringworm).² The application finally used (referred to as S.T.P.) was prepared as follows:

Thirty grains of sublimed sulphur were melted in a wide test-tube. To this, small quantities of oil of turpentine B.P. were added, well boiled, cooled by the addition of more turpentine, and decanted. This process was repeated until all the sulphur was dissolved, 6 fluid ounces of turpentine being used, and the volume made up to 8 fluid ounces with liquid paraffin B.P. The resultant preparation of sulphur, turpentine, and paraffin is a clear deep amber fluid with a pungent odour. The percentage of sulphur dissolved in the turpentine is about 1 per cent. If more is dissolved it crystallises out on cooling.

The three-day scheme of treatment, using S.T.P. in place of sulphur ointment, was adhered to, commenc-

ing with a single bath and scrubbing. Later this was found to be unnecessary and no attempt was made to open up burrows beyond that required for diagnostic purposes. In view of the observation made that vesicles will continue to form—apparently as irritative phenomena from fragments of sarcoptes left in the skin—the treatment, whenever possible, was completed with one or more baths and scrubbings to get rid of the dead parasites.

It soon became evident that S.T.P. was a more effective medicament than sulphur ointment, and had the initial netting of infected patients been complete the outbreak would rapidly have ended. As it was, in addition to one or two cases drafted from another block, fresh cases appeared both in the wards previously infected and in others. (This last fact is not surprising in view of the severe overcrowding, and the fact that structural defects of the block necessitate the constant intermingling of one ward with another.) The chief problem was no longer the treatment of the individual but the netting of the cases as yet undetectable. To do this, whenever scabies appeared the "hands and feet" examination of the ward was repeated at fortnightly intervals until two consecutive examinations were negative. Treated patients were re-examined more thoroughly and over a longer period. In this manner, after several phases of premature optimism, the outbreak was gradually quashed, the last four cases appearing in the early months of 1935. Doubtful cases should, of course, have been treated; but in view of the experimental nature of the treatment this was withheld until the disease was confirmed microscopically.

Many of the cases netted by systematic examination were very early ones. On the other hand, cases appearing in a ward not yet "scabies-minded" were often remarkably extensive, and this was particularly so in the wildly excited and resistive cases. Of 23 patients treated, 9 were cured after one course of treatment, 10 were cured after two courses. Of the remaining 4, 3 were cured on the third course and the other was treated and cured with Mitigal after the second failure of S.T.P. One other case was cured with Mitigal after failure with sulphur ointment, the choice of treatment being determined by the presence of a severe eczema of the legs.

Unpleasant results appear to have been confined to the appearance in two of the earlier cases of a crop

It is worth noting that of the total 29 patients, 13 exhibited scabetic lesions of the palm or sole. Of further interest is the fact that only one patient complained of itching, although several admitted this when questioned. One patient, an intelligent but depressed post-encephalitic, complained not of itching but of general ill-health. She was examined and found to have generalised scabies.

Table showing Survival Times of Adult Female Parasites in Different Media

Medium.	Number of experiments.	Viability.
Soft paraffin B.P.	1	44 hours. (46)
Sulphur ointment.. B.P.	4	5 11 18 26½ hours. (18½) (20½) (18) (28)
Mitigal	4	4 6½ 18 18½ hours. (6) (17½) (19) (21)
2 per cent. K ₂ S(fresh)	2	10 12½ min. (13) (15)
2 per cent. K ₂ S(stale)	1	70 min. (Sarcoptes lost.)
S.T.	3	5 5½ 7½ min. (5) (5½) (7½)
S.T.P. (1:1) ..	5	4 5 9 12½ 30 min. (5) (6) (11) (17) (33)
S.T.P. (1:4) ..	3	2½ 20½ 27 hours. (3½) (21½) (29½)

2 per cent. K₂S = 2 per cent. solution of sulphurated potash in water.

S.T. = 1 per cent. solution of sulphur in oil of turpentine B.P.

S.T.P. (1:1) = equal parts of S.T. and liquid paraffin B.P.
S.T.P. (1:4) = one part of S.T. to four parts liquid paraffin B.P.

EXPERIMENTAL OBSERVATIONS

The examination of the effect of various substances on the isolated living sarcoptes was suggested by the chance finding, in a scraping from a patient already under sulphur ointment treatment, of a vigorously active parasite completely embedded in sulphur ointment when the scraping was examined an hour or so after it had been obtained. From this time on, whenever a favourable case presented itself, examinations were made at the bedside on the living sarcoptes immediately after its capture from the patient. The parasite was at once mounted on a slide in the medium chosen, without any cover-glass, and examined under a low-power microscope. All but those which showed active movement at room temperature or on slight warming were discarded, and except for an occasional careful warming in the prolonged experiments (to supply evidence of continued life) all the experiments were carried out at a constant room temperature of between 60° and 70° F.

Considerable variation in vitality in a given medium was found, depending possibly upon the age of the parasite, but in spite of this a significant difference

Survival times of sarcoptes in various media (logarithmic scale).

of indolent boils. This was attributed to vigorous rubbing, which was subsequently avoided. Wherever possible the patient's urine was tested both before and after treatment, which was not intended for any case with kidney disease; but no such case was discovered, nor did any patient show albuminuria subsequently.

in viability in various media was found. The accompanying Table gives the observed viability of adult female parasites. For each medium the upper row of figures gives the time to the last observed sign of life, while the lower row gives the time to the observation of death. Any muscular movement, whether of

limb, jaw, or internal muscles, was regarded as a sign of life. Where observation was continuous the last observed movement was taken as the time of death.

If the survival times of the most viable examples in each medium are represented (roughly) on a logarithmic scale, giving the times between 1 minute and 64 hours, the results shown in the Figure are obtained.

No comparative experiments on the viability of the eggs were carried out. The following observations, however, are worth recording.

Eight eggs were captured and embedded in a film of sulphur ointment. They were left for four days at a temperature of about 60° F., at the end of which time four of the eggs were found to have hatched out, the larvæ having escaped.

Two eggs showing little differentiation of their contents were embedded in sulphur ointment. Each day they were put in an incubator at 100° F. for five minutes. One egg showed no further change. The other, on the fourth day, showed the distinct outline of the developing embryo. On the fifth day development appeared complete and slight warming resulted in repeated movements of the jaw. Hatching did not occur and on the following day there were no signs of life.

COMMENTARY

The object of this paper is to stress the inadequacy of sulphur ointment in the treatment of scabies rather than to advocate a new treatment which is far from ideal. It is not suggested that the experimental results with isolated parasites are strictly parallel with the activity of the medicaments concerned when applied to the skin; and in this connexion it should be mentioned that mitigal, which figures badly in the experiments, has been in the few cases in which I have tried it and in the experience of my colleagues an efficient preparation in the curing of scabies. In view, however, of the dogmatic optimism to be found in text-books of dermatology with regard to the treatment of scabies by sulphur ointment, the following of the recorded observations may well be emphasised:

Out of ten certain cases of scabies in mental patients not one was cured by two courses of sulphur ointment treatment.

A total of 33 courses of treatment resulted in five cures and five failures.

At room temperature an adult female sarcoptes will survive complete embedding in sulphur ointment for 24 hours.

At room temperature the eggs will survive and continue to develop for four days in sulphur ointment, and it does not prevent the larvæ hatching out. On the other hand, sulphur ointment is more lethal for the sarcoptes than Vaseline, killing the parasite in half the time.

Two per cent. sulphurated potash in water is markedly toxic for the parasite, but loses its potency if allowed to become neutralised by the carbon dioxide of the atmosphere. This fact prevented any satisfactory experiment with the reagent at the strength of the sulphurated potash bath as usually prescribed (i.e., about 1 in 1500).

Clinically S.T.P. (sulphur, turpentine, and paraffin) has been disappointing. Apparently potent when applied directly to the parasite at a concentration which caused little or no irritation to the skin, it frequently failed to cure the patient even when given as quite liberal applications on three successive days. On the other hand, for a certain type of patient it is undoubtedly superior to sulphur ointment. The treatment may be repeated the following week without ill-effect, and this course is probably advisable in any well-established case. The preparation is simple and cheap, and the opening-up of burrows, although

doubtless of benefit, is not an essential factor in the treatment.

I wish to thank the medical superintendent, Dr. C. J. Thomas, for his permission to publish these results, and my colleagues for their interest and help. I should also like to compliment the nursing staff on its cooperation in somewhat trying circumstances.

ANÆSTHESIA BY CLOSED METHOD

By T. A. B. HARRIS, M.B. Melb.

ANÆSTHETIST TO GUY'S HOSPITAL AND ST. PETER'S HOSPITAL
FOR STONE; ASSISTANT ANÆSTHETIST TO THE
WEST LONDON HOSPITAL

DISREPUTE has been brought upon the closed method of anæsthesia by excessive emphasis on its economy. It is certainly economical, but its importance lies in the exact and rational use that can be made of that hormone of the respiratory system, carbon dioxide.

USE OF THE SODA-LIME CANISTER

Failure to realise that economy is not the whole story has led to the adaptation of a soda-lime canister, often of faulty design, to a machine which has been designed for open anæsthesia. The result of this can only be a makeshift, often physiologically incorrect and therefore unsatisfactory. Closed anæsthesia is, as a result, condemned, although the real fault lies in an incorrect physiological design which renders a sound principle ineffective.

In order to apply the chemical principle of the absorption of carbon dioxide by soda-lime, a closed system of respiration is essential, and in such a system two factors must be fulfilled: (1) the carbon dioxide of each expiration must be completely absorbed; (2) the volume of oxygen used at each inspiration must be replaced by the introduction of a corresponding volume of oxygen.

One may employ a single-phase or a two-phase circuit of breathing. In the single-phase circuit, which is in effect an ebb-and-flow arrangement, the soda-lime canister is set between the mask and the bag. Breathing is from mask to bag and from bag to mask. One breathing tube is used and the direction of the air stream changes with inspiration and expiration. Both the inspired and the expired air are subjected to the resistance and chemical action of the soda-lime. In the two-phase circuit the expiratory and inspiratory phases run in the same direction. An expiratory and inspiratory one-way valve directs expiration from the mask through the soda-lime to the bag, whereas the inspiratory phase runs direct from the bag to the mask. Either circuit can be designed according to correct physiological principles, but the two-phase circuit makes it easier to combine correct physiological with convenient mechanical principles, and a more flexible unit is possible.

Volatile anæsthetic agents are excreted by the lungs almost completely, and in exactly the same form as that in which they were absorbed. In a closed system, therefore, the same amount of anæsthetic may be cleansed and used again and again. In designing such a system five factors are of importance: (1) the system must be airtight; (2) resistance to breathing must be reduced to the smallest possible proportions; (3) the absorptive properties of the soda-lime must always be active; (4) artificial dead

space must be reduced to the smallest possible volume; (5) the oxygen supply must be fed into the system in such a manner as to be easily adjusted and readily available.

Airtightness.—If an endotracheal tube is used with adequate packing no difficulty is experienced in rendering the system airtight. A mask accurately adjusted and held in position with Clauson's harness will almost invariably make an airtight joint. A method of neutralising a slight leak between the mask and the face will be mentioned later.

Resistance to breathing.—There are three possible sources of resistance: (1) The weight and resistance of the expiratory and inspiratory valves, which can readily be reduced to a minimum. (2) The design of the canister and the size of the soda-lime granules employed; the smaller the granules the greater will be their absorptive powers but the greater will also be their resistance to breathing. Since the size of the canister is of little moment one can afford to increase the size of the granules to that mesh which provides efficient absorption and at the same time gives least resistance to breathing; using my form of divided canister, that known as 6-10 mesh, is most satisfactory. (3) The ether reservoir; if this is designed on the carburettor-wick principle resistance is very slight and is of little importance, because it is in circuit for such short periods of time. The total resistance to breathing in the machine I use is 2 mm. of Hg.

Absorptive properties of the soda-lime.—If the anaesthetist uses Siebe Gorman's Green Protosorb in a glass canister he can determine the integrity of the charge of soda-lime at any period, since it changes in colour from green to grey-brown when its absorptive properties have become depleted. In a two-phase circuit the flow through the canister is in one direction only, and he can therefore follow colorimetrically the gradual depletion of the canister contents from entrance to exit as the anaesthetic proceeds. If the divided canister is used as soon as the soda-lime becomes depleted the canister can be by-passed, recharged, and replaced. The use of coloured soda-lime and the possibility of recharging the canister during the anaesthetic makes the chance of inefficient absorption very remote.

Dead space.—On the question of dead space hangs the flexibility and physiological integrity of this method of anaesthesia. The normal volume of tidal air is 500 c.cm. and the normal volume of respiratory dead space is 140 c.cm. The difference between these two values—i.e., that volume of the inspiratory air which actually reaches the lung alveoli and can take part in respiratory exchange—is 360 c.cm. This will be referred to as "efficient lung ventilation."

Tidal air.	} Minus {	Dead space.	} Equals {	Efficient lung
500 c.cm.		140 c.cm.		ventilation.

The volume of efficient lung ventilation can be reduced in two ways: (1) by reducing the volume of tidal air; (2) by an artificial increase in the volume of dead space. The factors which reduce the volume of tidal air and the methods of correcting them are common to both the open and the closed methods of anaesthesia. The problem of artificial increase of dead space applies particularly to closed anaesthesia. It is easy to visualise an increase of artificial dead space which would reduce the volume of efficient lung ventilation to zero. In such an event the protective respiratory reflex would effect a compensation to the extent of 1500 c.cm., the volume of complementary and supplemental air; but if the volume of artificial dead space were increased beyond 3000 c.cm. no amount of compensation could render efficient lung ventilation possible. It may be objected that machines are to be seen whose artificial dead space ranges up to, and even exceeds, 3000 c.cm., and that they function. This is true; even in the face of such a huge dead space, an apparently insuperable obstacle, respiratory exchange can be effected. However great the volume of artificial dead space between the lung alveoli and the source of supply, gaseous equilibrium will eventually be reached between the two, by the physical process of diffusion of gases, but before this equilibrium has been reached the patient will have experienced a period of respiratory discomfort, depending in duration and severity upon the

volume of artificial dead space present. It is essential, if physiological principles are to be reproduced, that the volume of artificial dead space be reduced to the smallest possible proportions. The greater the volume of efficient lung ventilation, the more flexible will be the method, and since, in anaesthesia, everything is conspiring against the maintenance of a large tidal air volume, it is the more imperative that artificial dead space be kept as small as is mechanically possible.

As rebreathing plays such a part in the administration of gaseous anaesthetics in the open methods, what will be the effect of reducing the volume of artificial dead space to zero? The body has no difficulty, in the presence of an adequate supply of oxygen, in maintaining a normal alveolar carbon dioxide content in the presence of an atmosphere containing no carbon dioxide at all. Increased lung ventilation, with consequent fall in alveolar carbon dioxide content, produces apnoea which will continue until alveolar carbon dioxide is raised to normal physiological limits when, in the presence of an adequate supply of oxygen, breathing will be resumed without periodicity. But because of the depressing effects of anaesthetic agents, because of the toxic and shocked condition of many anaesthetised subjects, it is not wise to depend upon the body's protective reactions, but rather to use the stimulating action of added carbon dioxide whenever it is clinically indicated. By means of a by-pass on the soda-lime canister the carbon dioxide content of the system can be rapidly and readily built up to the desired level without upsetting the physiological balance. There is no reason, therefore, if a by-pass is provided on the canister, why the volume of artificial dead space should not be reduced to zero. It is imperative, in a closed system of anaesthesia, that artificial dead space be reduced to the smallest possible proportions, and that a by-pass be provided on the canister for the therapeutic use of carbon dioxide.

Oxygen supply.—Once anaesthetic equilibrium has been attained at the depth required, the metabolic rate of the patient is almost constant and the patient's blood is in gaseous equilibrium with the contents of the closed system. The pressure in the system at this point, as read on the manometer, is a numerical index of the depth of anaesthesia, and if this pressure is kept constant the level of anaesthesia will remain stationary. Anaesthetic agents are excreted almost completely and in exactly the same form as that in which they were absorbed. Consequently no loss of pressure will result as far as they are concerned. Because the system is closed it is essential that the carbon dioxide of each expiration should be completely absorbed by the soda-lime, and that the volume of oxygen used with each inspiratory effort should be replaced by the introduction of a corresponding volume of oxygen. The absorption of the carbon dioxide will cause a fall in pressure in the closed system, but because the metabolic rate is constant, the output of carbon dioxide, and the consequent fall in pressure due to its absorption, will be a constant fixed value. The volume of oxygen necessary for replacement will therefore be that amount which will neutralise the fall in pressure caused by the absorption of carbon dioxide. It will also be a constant fixed amount. Having attained anaesthetic equilibrium, the amount of oxygen necessary to maintain the partial-pressure constant will be the greatest amount that will not cause a rise in pressure in the closed system. This amount of oxygen will be the correct volume only if it is fed into the system in such a manner that it is all available with each inspiratory effort. The possibility of oxygen being backwashed and remaining in the system to dilute the anaesthetic contents must be averted. This is achieved if the oxygen is fed into the inspiratory flow of a two-phase circuit as near the mask as possible, a method which allows of a rapid and minute control of oxygen, with ease of adjustment, and which, in an emergency, makes it possible to deliver oxygen direct to the patient.

These five factors are the bare essentials which must be satisfied if a closed system of anaesthesia is to conform to correct physiological principles. An additional principle presents itself, which while not essential to the success of the method makes for ease

of control. With the patient in anæsthetic equilibrium, the oxygen inflow adjusted, the carbon dioxide being absorbed, and the system efficiently closed, the third factor, the partial pressure of the anæsthetic agent in the system will also remain constant and the depth of anæsthesia will consequently be maintained at a fixed level. The pressure in the system is lowest on inspiration and highest at expiration. One must take the inspiratory pressure as the true or actual pressure at which one is working, and the difference between this and the expiratory pressure as simply a measure of the amplitude of respiratory movement. If a slight leak occurs—the junction of the mask with the face is the only probable site—the pressure in the system will gradually fall and the depth of anæsthesia will gradually lighten. The leak, when present, occurs during expiration when the pressure is greatest. This is important because the gases to be lost are then chiefly carbon dioxide and anæsthetic agents. If the leak occurred during the inspiratory phase the oxygen regulation would be seriously interfered with.

The loss of carbon dioxide during expiration is of little moment, for it must be excreted and it does not matter whether it is absorbed by the soda-lime or lost into the atmosphere. The loss of anæsthetic agent is of great importance; it must be replaced if the depth of anæsthesia is to remain steady. A lever system controlling the flow of anæsthetic agent from the source of supply to the bag will achieve this object. The screw adjustment can be set to allow anæsthetic agent to flow into the system only when the pressure falls below the predetermined inspiratory pressure. By this means the lever system will automatically allow just so much anæsthetic agent to flow into the closed system as has been lost by the leak, and the pressure of anæsthetic agent is maintained at any predetermined pressure. A machine so designed will conform to correct physiological principles, and once adjusted to the depth of anæsthesia required will regulate itself with the same flexibility as any open anæsthetic machine.

GENERAL CONSIDERATIONS

Inferior samples of soda-lime contain an excessive amount of caustic and as a result cause a dry mouth and throat, and even tracheitis. They may also pulverise to form a fine alkaline dust which causes an irritating cough during induction. I find that this annoying complication is eliminated only when I use Siebe Gorman's protosorb. Protosorb becomes harder on use and does not cause excessive dehydration. After an anæsthetic of one hour's duration 3-4 drachms of water will be found in the bag of my machine, its most dependant part. This saturated water vapour content of the system is beneficial. In filling the canister an air space should be left above the soda-lime on the inlet side to enable the gases to spread out and so diffuse evenly throughout the canister contents.

The use of an outside source of carbon dioxide is neither necessary or desirable; the by-pass on the canister will provide all that may be required. The chemical action of carbon dioxide on soda-lime generates heat. An outside source of carbon dioxide will waste the soda-lime and generate excessive heat. By its use temperatures of up to 45° C. have been registered in the canister. When the by-pass was used to obtain carbon dioxide, even with excessive respiratory effort the temperature has never exceeded 38° C., and, with the bag and the length of the inspiratory phase to act as distributors of heat, the temperature in the mask has never exceeded 37° C. The heating

of gases is adequate but not excessive if the by-pass is used. The alkalinity and filtering action of the soda-lime renders the system bacteriologically sterile, and the closed system makes the possibility of anæsthetic explosions very remote.¹

The economy is striking. Anæsthetic agents are lost only during induction when the system is open in order to eliminate nitrogen. From this time onwards the replacement which may be necessary due to leakage is very small. During two operating days at St. Peter's Hospital, the measured quantities used for twelve cases, two of which were short open anæsthetics, were:—

Nitrous oxide	..	..	100 gals.	5s. 8d.
Oxygen	..	..	120 "	5s. 0d.
Ether	..	..	16 oz.	5s. 0d.
Soda-lime	..	..	5½ lb.	6s. 6d.

This is equivalent to a cost of 1s. 10d. per anæsthetic. Using 6-10 mesh, my canister takes a charge of ¾ lb. of soda-lime, which is sufficient for an anæsthetic lasting from one to one and a half hours, depending on the patient's metabolic rate.

CLINICAL FACTORS

The accompanying Figure is a diagrammatic representation of the two-phase circuit. There is a clear-cut expiratory phase from the mask to the bag with the soda-lime in series. This ensures that the bag will contain oxygen and anæsthetic agent at the pre-

Diagram of the closed circuit.

determined pressure, plus just that amount of carbon dioxide which has been determined by the use of the by-pass. The inspiratory phase is straight from the bag to the mask, picking up its quota of oxygen necessary for replacement high up in the inspiratory flow. An ether reservoir and a gas-regulating valve are set in series. The contents of the bag and the incoming oxygen are communicated to the patient with the very next inspiration as the volume of efficient lung ventilation is as high as possible, and thus control is very flexible. The machine I use has four controls: a valve regulating the proportions of nitrous oxide and oxygen; a carbon dioxide absorber, which can be turned on or off; an ether control which can be turned on or off; a pressure-adjustment screw to regulate the pressure, with a manometer and an expiratory valve on the mask.

Induction is invariably carried out with nitrous oxide irrespective of what sequence is to follow. With the expiratory valve on the mask open and the soda-lime by-passed the machine is a simple open apparatus.

The oxygen and nitrous oxide having been turned on at the source of supply, the mask is applied and the

¹ Harris, T. A. B.: Brit. Med. Jour., 1933, II., 1203.

regulating valve turned to full nitrous oxide. As induction proceeds oxygen is cautiously added with this regulating valve. After 10 to 15 expirations the nitrogen which was present in the machine and the pulmonary system has been excreted through the expiratory valve on the mask. An airway is inserted, the mask accurately adjusted and fixed with Clauson's harness, and the machine is closed by shutting tightly the expiratory valve on the mask. Should carbon dioxide be required to hasten induction the carbon dioxide absorber valve is left in place, and when this has been achieved it is turned to the "on" position and the absorption of carbon dioxide begins. The pressure is then adjusted by means of the screw on the lever system to the clinical requirements, and the oxygen inflow accurately controlled by means of the regulating valve to an amount which will not increase this predetermined pressure. Ether is added if relaxation is needed. The pressure and the amplitude of respiratory movement are noted for future reference. From this time onwards nitrous oxide is regulated by the lever system, oxygen is regulated to the patient's metabolic rate, and carbon dioxide absorption is complete.

Most information is gained from the manometer. A rise in pressure can be due to two causes.

(a) The inefficient absorption of carbon dioxide. There is no excuse for this occurring, for the change in colour of the protosorb in the glass canister gives ample warning. Should it occur the expiratory valve on the mask is opened and the carbon dioxide absorber valve is turned to the "off" position, when the canister can be removed, recharged, replaced, the system closed again and absorption recommenced.

(b) If the soda-lime is efficient then a rise in pressure will be due to a too great supply of oxygen. More oxygen is being supplied than is necessary for replacement. The oxygen supply must be reduced by the regulating valve until the pressure as recorded on the manometer returns to its predetermined reading or the colour begins to fail, when the oxygen supply is more carefully adjusted.

The amplitude of swing of the manometer needle tells of the activity of the respiratory centre. Should the amplitude of swing fall below 3 mm. of mercury the carbon dioxide absorber valve is turned to the "off" position, when carbon dioxide rapidly accumulates in the system with the desired clinical result. It is important to keep respiratory movements within normal limits. A reduction of respiratory movement means a depressed respiratory centre, but in addition this diminution of movement hinders the efficient filling of the right heart, and cardiac output is reduced with a fall of blood pressure which materially embarrasses an already depressed respiratory centre. Depth of anaesthesia can be rapidly lightened by reducing the pressure in the system, this reduction can be made delicately if the manometer is referred to during the adjustment. Anaesthetic equilibrium having been reached at the depth required the machine will regulate itself and the manometer will, in the presence of a clear airway, give the exact and adequate information necessary for the protection of the patient.

Should the anaesthetic be prolonged, or the patient be a poor subject, the complication of an altered susceptibility appears. This ranges in relative intensity, from mere depression of the respiratory and cardiovascular systems to established surgical shock. Depression, as indicated by the irregular or reduced amplitude of respiratory excursions, is countered by an increase in the carbon dioxide content. It is necessary to overcompensate, but when the increased breathing returns to normal the body will maintain the correct physiological alveolar carbon dioxide content for some considerable time. The continuous by-passing of even small amounts of carbon dioxide

is incorrect, but as the depression becomes more intense the anaesthetist will make more frequent use of the by-pass valve and may even decrease the pressure in the system. As the depression increases in degree, in addition to the use of carbon dioxide, he will have to increase the supply of oxygen. Thus as anaesthesia proceeds two states preceding shock can be recognised, one of which carbon dioxide will hold in check, and the second which requires, in addition to carbon dioxide, an increase in the oxygen supply. If these states are recognised comparatively early, this technique will arrest their onset.

When, however, the exhibition of carbon dioxide and excess of oxygen fail to relieve the condition, surgical shock is definitely established. The patient's susceptibility to anaesthetic agents is definitely raised, and one must reduce the pressure in the system—that is, reduce the partial pressure of anaesthetic agents or the anaesthetic contents of the system—and take the necessary therapeutic measures to counter this shock. The clinical condition of shallow and irregular breathing, inspiratory tugging, a fall of blood pressure, and a soft and rapid pulse may indicate three errors: (1) respiratory depression due to faulty absorption of carbon dioxide; this is readily diagnosed; (2) a bad airway; by listening with the breathing tubes held close to the ear one can easily determine this fault; (3) nitrogen in the system; if the expiratory valve on the mask is opened for 10 to 15 expirations any nitrogen present will be excreted. If, after these manoeuvres, this syndrome is not relieved then advanced surgical shock is established.

An increase in pressure in the system when nitrous oxide and oxygen alone are being used will increase depth of anaesthesia only within narrow limits, but if a lipid soluble anaesthetic is employed it offers a very effective means of increasing depth. At the same time I do not consider this to be the method of choice; I believe that the smallest satisfactory pressure is the correct one, and work usually at from 4 mm. to 7 mm. of mercury. Carbon dioxide is used only when it is clinically indicated, and not more or less empirically, as in open anaesthesia. It is my impression that the excessive use of this powerful respiratory stimulant in open anaesthesia is responsible for the unwarranted shock which sometimes follows a N_2O oxygen anaesthetic. By the use of constant rebreathing one is in effect "whipping a tired horse." In closed anaesthesia, on the contrary, with a machine of correct physiological design, carbon dioxide is used only as the clinical condition of the patient indicates. The anaesthetic which results is smooth, with quiet breathing, and one is struck by the pink colour which it is possible to maintain throughout. Relaxation is achieved with a minimum of toxic anaesthetic agent, and recovery is consequently rapid and can be materially hastened by a reduction of pressure and the use of carbon dioxide.

In my opinion, if the physiological principles outlined above are satisfied, the anaesthetic which results will be more physiologically correct than it is possible to achieve with open methods. Heat loss is at a minimum, the water vapour content is always saturated, cyanosis should never occur, and, because the oxygen supply must always be adequate if the system is to function, relaxation is attained with a minimum of toxic anaesthetic agent the elimination of which is correspondingly rapid, so that the patient's cough reflex is almost always present before leaving the theatre. Moreover, a machine fulfilling these conditions is flexible to manipulate.

TREATMENT OF COLLES'S FRACTURE

By E. A. DEVENISH, M.S. Lond., F.R.C.S. Eng.

ASSISTANT IN THE SURGICAL UNIT, UNIVERSITY COLLEGE HOSPITAL

BRIEFLY the principles of treatment of Colles's fracture are reduction, fixation of the fragments, and early active movements of the fingers. Reduction is usually effected either by the shaking-hands method or by the method of Robert Jones. The position in which the wrist-joint should be fixed has been much discussed and in this country one of two positions is commonly employed.

In the first a Carr's splint is applied, the wrist-joint being slightly dorsiflexed; in the second, the wrist is held in a position of plantar flexion and ulnar deviation, usually by the application of a plaster splint. When a Carr's splint is used, unless the fracture happens to be one in which the reduction is stable, the displacements are liable to recur. Moreover Carr's splint is a clumsy piece of apparatus, and though the patient can move his fingers that is the utmost he can do with the affected hand. When the wrist is fixed in full flexion and ulnar deviation the displacements are unlikely to recur as long as this position is maintained, but active movements of the fingers are very difficult. Another and more serious drawback to this position of the wrist is that it may sometimes result in a median neuritis.¹

Böhler's method of treating Colles's fracture consists of reduction by steady manual traction in the long axis of the forearm and fixation of the fragments by an unpadded plaster splint with the wrist-joint in such a position that the dorsa of the hand and of the forearm are in a straight line. This allows free movement of the fingers and the patient can use his hand, but a consideration of the anatomy of the capsule of the wrist-joint and of its ligaments will show that by this method complete restoration of the normal anatomy of the radius is impossible. The best result obtainable is that the distal articular surface of the radius is at right angles to the long axis of the forearm. In spite of this it is a better method than either of those previously described, as secure fixation of the fragments is effected, the patient can still carry out active movements of the fingers, and can use his hand from the very beginning of treatment.

Acting on the belief that accurate re-position of the fragments was essential, and bearing in mind the importance of early active movement, a method was devised to secure both those objects. The patients were fully anaesthetised by open ether. Reduction of the fracture was effected by the shaking-hands method, with care to make sure that the lower fragment was disimpacted. The problem then was to keep the lower fragment accurately in position while applying a plaster splint which would fix the wrist-joint with the dorsum of the hand and of the forearm in line. This was solved by the use of a spat as follows:—

A loop of 1½ in. bandage was placed over the forearm so that it rested over the lower fragment. Into the rest of the loop, which should be almost but not quite long enough to reach the floor, the operator placed his foot. The fully pronated forearm was then supported on an inclined plane, made of two or three small sand-bags, which rested on a small table level with that on which the patient was lying and placed alongside it. The

fingers were gently pulled upon by one hand of an assistant, so as to keep the wrist-joint in the position previously described, while with his other hand the assistant held down the forearm near the elbow. By gentle pressure with his foot in the loop of bandage the operator maintained the corrected position of the lower fragment while the splint was being applied. This was an unpadded plaster splint and consisted of a dorsal slab, extending from the level of the knuckles to just below the elbow-joint, held in place by a circular plaster bandage. The wrist-joint was included in the plaster and the hand fixed to the dorsal slab by a strip of plaster which crossed the palm of the hand obliquely so as to allow full flexion of the metacarpo-phalangeal joints. The forearm was of course lifted by the assistant while the circular bandage was being applied. The essential point of the technique is that moulding of the plaster round the lower end of the forearm and the wrist-joint should be accurately carried out; in particular the plaster should fit well into the depression produced by the spat, on the dorsum of the wrist-joint. As soon as the plaster had set the bandage was cut off close to the plaster. A glance at the diagram will illustrate the points mentioned. Two 4 in. plaster bandages 3 yards long were used to make the splint. When swelling of the wrist was so marked as to cause anxiety, the patient was kept under observation for

24 hours after the application of the plaster, the limb during this time being elevated. X rays were taken before and after reduction, and an X ray should be taken at the end of a week to see whether the fragments are still in position, as in those cases in which considerable swelling is present when the plaster is applied, slipping of the fragments is apt to occur as the swelling subsides and the plaster become slack. Should this have occurred it is not yet too late to re-correct the fragments and apply another plaster. Active movements of the fingers and the use of the hand were encouraged from the start of treatment and massage was not employed.

Nine patients, all women, six of whom were over 60 and the remaining three 45 years or over, were treated during January–June of 1934. They were asked to come to hospital to be examined in January of this year. Six of them did so, two did not reply, and one wrote in reply to the follow-up letter. In three cases the lower fragment was found to have slipped back. This was discovered in two of these when X rays were taken 18 days and 9 days respectively after the application of the plaster. In both there had been an interval—four days in one case and three days in the other—between the fracture and the reduction, and there was considerable swelling of the wrist-joint at the time of reduction. The third case had the following history:—

F.74. Fracture 15/2/34. Reduced 16/2/34. Plaster changed two weeks after reduction and taken off altogether a week later. She was discharged a week later—i.e., four weeks after the fracture—with full movements of the fingers and wrist, except for 20° limitation of full extension and slight limitation of supination. She was seen 11

¹ Cabot and Saunders: Surg., Gyn., and Obst., 1933, Iviii, 207–516.

months later and X rayed. The function of the hand was good, the grip was equal to that of the opposite hand, she had no pain in the wrist, and there was slight limitation of flexion and supination. The X ray showed that the lower fragment had rotated backward.

These cases illustrate the need of X raying the wrist at the end of a week as a routine, or sooner if the plaster has become slack. Of the remaining six patients, slight over-correction of the lower fragment had occurred in four of them. This had had no ill-effect on the ultimate result, as two of them who were seen nine months after the fracture had no limitation of any movement in the wrist-joint or of pronation or supination. The third wrote to say that she had no trouble with the wrist. A feature which was observed in four of the cases treated was a shortening of the lower end of the radius resulting in a subluxation of the distal radio-ulnar joint. This was not due to a recurrence of the deformity as in all these cases the lateral X rays showed that the backward rotation and displacement had not recurred. The fourth case illustrates this point:—

F.61. Left Colles's fracture 24/4/34. X ray before reduction showed considerable backward rotation and displacement with subluxation of the distal radio-ulnar joint. Reduced 24/4/34. X ray after reduction showed that an almost perfect anatomical repair had been attained. An X ray taken on 18/5/34—i.e., 24 days after the date of the fracture—and its reduction, with the original plaster still in situ, showed that in the A.P. view the radius seems to have shortened a little and the subluxation of the distal radio-ulnar joint has recurred. The lateral view shows that no recurrence of the backward displacement nor of the backward rotation has occurred. The plaster was removed 36 days after reduction and the patient was discharged two weeks later—i.e., nearly six weeks after the date of the fracture—with good movements. She was seen and X rayed nine months after the date of the fracture. The function of the hand and the grip was as good as that of the opposite hand. The only loss of movement was slight limitation of pronation. There was no pain at the wrist.

A frequent association was observed between subluxation of the distal radio-ulnar joint and pain over the region of the head of the ulna, but this pain did not persist and disappeared in the course of time. Thus of five cases in which subluxation of the distal radio-ulnar joint was present and produced either by shortening of the radius after reduction or by failure to correct this deformity adequately, three when seen nine months after had no pain in the wrist, and the only abnormality as far as movement was concerned was slight limitation of pronation in one of them. Subluxation of the distal radio-ulnar joint was demonstrated to be present by X rays taken then. The fourth wrote to say that she had no pain in the wrist-joint. The fifth case was as follows:—

F.65. Right Colles's fracture 4/4/34. X ray showed extensive comminution of the lower fragment extending into the wrist-joint, with considerable backward rotation and displacement, fracture of ulnar styloid, and subluxation of the distal radio-ulnar joint. Reduced 4/4/34, slight over-correction of the antero-posterior displacements; subluxation of distal radio-ulnar joints, not fully corrected. 27/4/34: plaster removed (23 days). X ray showed lower fragment still slightly over-corrected, but shortening of the radius with an increase in the degree of subluxation of the distal radio-ulnar joint had taken place. The patient attended the fracture clinic for a further three and a half months. 15/3/35 (11 months): dorsiflexion full, flexion slightly limited, pronation full, minimal limitation of supination. The grip was good

and the hand was quite useful. On prolonged gripping the patient gets pain over the lower end of the ulna in proximal to the styloid process. Flexion of the fingers was not quite perfect and the pain over the lower end of the ulna was worse in cold weather.

An X ray showed osteo-arthritic changes in the radio-carpal and distal radio-ulnar joints, and there was a considerable degree of subluxation of the distal radio-ulnar joint present. It seems likely that her arthritis was produced by the damage to the wrist-joint and that the residual pain is due to the arthritis and not to the subluxation of the distal radio-ulnar joint.

It was found possible to retain the original plaster for periods which varied between 2 weeks and 36 days, and with two exceptions the patients were discharged from 4-7 weeks after the date of the fracture.

I should like to express my indebtedness to Mr. Gwynne Williams and Prof. C. C. Choyce for help and criticism, to Mr. C. W. Flemming and Mr. Williams for permission to publish this account of cases under their care, and to Miss M. Scott for the diagram.

CONGENITAL ATRESIA OF THE DUODENUM

IN A CHILD AGED THIRTEEN MONTHS

By T. G. D. BONAR, M.D., M.S. Lond.

HON. SURGEON TO THE EVELINA HOSPITAL FOR CHILDREN, LONDON

CONGENITAL atresia of the duodenum is a comparatively rare condition, and the following case may be of some interest.

REPORT OF CASE

A girl, aged 13 months, was admitted under my care to the Evelina Hospital for Children because of vomiting, which began on Feb. 28th for the first time. On that day she vomited her food twice, but no bile was noticed by her mother and she did not seem to be in any pain. The bowels had acted once. The child had always enjoyed good health and had been breast-fed up to the age of

8 months. On March 1st she vomited her food three times, but nothing else abnormal was noted by the mother. She passed a normal motion. On March 2nd she vomited several times and so the mother decided to bring the child to hospital, particularly as she had noticed "swelling of its stomach." The bowels had been opened.

On admission the child looked very ill and was vomiting every few minutes a watery fluid which was not bile-stained. The vomiting was projectile and was preceded and accompanied by signs of abdominal colic—screaming and drawing-up of the legs. On examination it was noticed that the child had obliquely set palpebral fissures and a long protruding tongue and was edentulous. There were

signs of serious dehydration, the eyes were shrunken, the anterior fontanelles depressed, and the skin and tongue dry. There was great distension of the upper abdomen, and also down the right side to the iliac fossa. Large peristaltic waves could be seen commencing at the left subcostal region passing to the right hypochondrium and then to the right iliac fossa. Usually there were about three waves every minute, but on occasions and following abdominal palpation a second wave made its appearance before the preceding one had disappeared. At other times no waves were seen for several minutes; with the onset of each wave the child drew up its legs and screamed. At intervals of 3-5 minutes the child vomited in a projectile manner. The tense appearance of the upper and right quadrants of the abdomen was confirmed on palpation. The pylorus was not palpable. A succussion splash was heard. No free fluid was demonstrable. Rectal examination was negative. Heart: not enlarged; sounds

FIG. 2

normal. Pulse: 150, regular; volume poor. Lungs: no dullness; breath sounds normal.

A diagnosis was made of acute obstruction supervening on chronic obstruction in the duodenum. Immediate operation was decided on.

Operation.—Under gas-and-oxygen, a small quantity of ether being given for opening and closing the peritoneal cavity, a supra-umbilical right paramedian incision was made, the rectus being drawn laterally and the peritoneum opened. The stomach and the first and second parts of the duodenum were found to be enormously distended, so much so that the caecum and ascending colon were lifted anteriorly by the distended duodenum. There was a distinct whitish, constricted area a few millimetres wide, running transversely in the wall of the duodenum dividing the dilated proximal part from the normal, but collapsed, distal portion of the duodenum. At this point the duodenum was crossed by the superior mesenteric vessels ensheathed in dense fibrous tissue forming a raised white fibrous band extending on to the anterior surface of the caecum. The constricted area on the duodenum, on macroscopic examination, suggested that fibrotic changes had set in. There were some enlarged glands on the surface of the head of the pancreas which did not appear to be rotated. There were also glands in the mesocolon in close relation to the branches of the arteries.

and glands were especially noticed in the mesentery of the small intestine.

A duodeno-duodenostomy was considered but was found to be impossible and a duodeno-jejunostomy was also

FIG. 3

found to be impracticable because of the enlarged glands on the head of the pancreas. A posterior gastro-jejunostomy was carried out—as advocated by Downes, Max Page, and others—but the obstruction appeared so complete that pyloric occlusion, which is advocated in addition by some surgeons, was deemed unwise. This operation was carried out as expeditiously as possible and without difficulty; the wound was closed in layers. It took 25 minutes and saline was given subcutaneously. The condition of the child on returning to bed was extremely grave. Some hours after the operation the child died.

Post-mortem examination was carried out the next day. No abnormalities were discovered in the lungs, heart, liver, spleen, small and large intestine, or kidneys. The stomach, duodenum, pancreas, and the gastro-jejunostomy were removed in one piece, together with the caecum, ascending and transverse colon. On laying open the stomach, which was dilated, the walls were found to be hypertrophied. The pylorus was open. The duodenum was dilated as far as the stricture, and the walls above the level of the stricture were also slightly hypertrophied. The mucous membrane was congested in both the stomach and duodenum.

The stricture in the duodenum was found to encircle it completely and measured in breadth about 2 mm. It appeared fibrotic and extended throughout all coats of the duodenum so that there was a fibrotic area, surrounded by mucous membrane, on the mucous side of the bowel. This strictured area was exactly at the point where the superior mesenteric vessels passed over the duodenum. The pancreas appeared

normal and the superior mesenteric vessels were in their normal anatomical situation. On the head of the pancreas were some very enlarged lymphatic glands. Macroscopically these showed inflammatory changes. A long but very definite fibrotic band ensheathed the superior mesenteric vessels and running downwards to the right ended on the anterior surface of the caecum. Enlarged glands, inflammatory in type, were found in the transverse mesocolon and also in the mesentery of the small intestine. There was no sign of tuberculosis.

FIG. 4.—Congenital occlusion of the transverse part of the duodenum at the point at which the me-enteric vessels cross. Note the extreme distension of the proximal portion of the duodenum. (From "Surgical Emergencies in Children," Baillière, Tindall and Cox, in the press.)

Dissection of the specimen.—My house surgeon, Dr. N. Townsley, made a difficult dissection of the duodenum and pancreas to demonstrate the common bile-duct and the pancreatic duct. The dissection showed that the ampulla of Vater was situated in the distal part of the duodenum, immediately beyond the stricture. The pancreatic duct seemed to enter at the same site. It was interesting to note that the common bile-duct passed directly downwards through the substance of the pancreas and in the same axis into the duodenum, appearing from the outside as if it were going to enter at the site of stricture. No rotation of the pancreas was apparent, and this seemed to prove that as the second part of the duodenum gradually became dilated it had not rotated downwards carrying the head of the pancreas with it. Microscopical section of the stricture showed that the mucous membrane, muscular and peritoneal coats in the area were replaced by fibrous tissue. An attempt to get a fine tube through the stricture failed.

The accompanying sketches of the dissection (Figs. 1-4) will perhaps explain more clearly what was found.

ÆTIOLOGY OF THE CONDITION

Congenital atresia of the duodenum was first described by Calder¹ in 1733. Davis and Poynter² collected 392 cases of congenital occlusion of the intestine between the pylorus and the rectum; a single atresia of the duodenum or jejunum was found in 194, and in 134 of these it was in the duodenum. Out of 184 cases of congenital occlusion of the intestine collected by Kuliga,³ 46 were in the duodenum. Schlegel, quoted by Braun, found that the occlusion was in the duodenum in 32.5 per cent. of cases, usually in the region of the ampulla of Vater, but occasionally at the junction of the duodenum and jejunum (Cordes,⁴ 5 out of 57 cases).

Cautley⁵ distinguishes two groups in which the defect is in the neighbourhood of the ampulla of Vater (67 out of 92 cases investigated by Spriggs) in one and usually at the level of the duodeno-jejunal flexure in the other. The first is subdivided into cases occurring above, opposite or below the papilla. Cordes⁴ says that in his series 20 instances were above the papilla (10 of these were immediately above), 6 were opposite the papilla, and 13 below the papilla. Cautley emphasises that mere narrowing—i.e., annular constriction partially or entirely obliterating the lumen—is very rare.

Jewesbury⁶ quotes 2 cases of duodenal obstruction in infants. In one the stricture was between the second and third portions of the duodenum, but there was no evidence of compression from the surrounding strictures; and in the other it was at the level of the duodeno-jejunal junction. In this case the cæcum was high (as in the case here reported), and the obstruction was caused by pressure from outside and in particular the right colic artery.

In the case I have described above it was noticed that the site of obstruction was exactly where the superior mesenteric vessels crossed the duodenum, and at the time of operation the case was thought to be one similar to that described by Downes,⁷ who noticed on X ray examination the obstruction ended abruptly at the site of the superior mesenteric artery; but it was difficult in my case to say why no bile had appeared even in the vomit. This was accounted for post mortem, when it was noted that the common bile-duct ran directly downwards from the superior to the inferior borders of the pancreas and opened directly on to the postero-superior aspect of the duodenum, beyond the stricture.

The operation was also of interest. The ideal seemed to be either a duodenoduodenostomy or a duodenojejunosomy. Mention has already been made of how impossible it was to do either of these

and one was compelled to carry out a posterior gastrojejunostomy. This agreed with the operation advocated by others—namely, a gastro-enterostomy with or without pyloric occlusion.

It appears that in this case the atresia was gradually becoming more and more complete and the superior mesenteric vessels were only incidental in completing the onset of an acute obstruction.

According to Tandler,⁸ Forssner,⁹ and Huerter,¹⁰ the Vaterian segment of the duodenum is occluded by epithelial proliferation during the second month of foetal life and atresia is due to failure of the plug to break down or become canalised. In my case canalisation had apparently taken place, but one area had become replaced by fibrous tissue which had gradually but surely led to atresia, which had contracted down leading to the onset of the acute obstruction.

I am indebted to Mr. Harold Edwards for allowing me to reproduce the drawing (Fig. 4) illustrating this case, which he had made for his book "Surgical Emergencies in Children," to be published shortly.

Clinical and Laboratory Notes

MONOCYTIC (HISTIOCYTIC) LEUKÆMIA

By T. N. GLEDHILL, B.A. Oxon., M.R.C.S. Eng.

ASSISTANT PATHOLOGIST, L.C.C. GROUP LABORATORY,
LAMBETH HOSPITAL

THE subject of monocytic leukæmia and reticulo-endothelioses in general has recently attracted a good deal of attention, and Ross¹ states that 22 histologically authenticated cases are on record. The one here described cannot be included in the group of histologically authenticated cases, for, to the best of my knowledge, the patient is still alive; he removed from the district in which he was living and repeated inquiries have failed to trace his present abode. Nevertheless, I think the blood picture as here presented leaves no doubt that the case was one of monocytic leukæmia.

A man aged 48, a canvasser, was admitted to Lambeth Hospital on August 17th, 1933, complaining of shortness of breath, palpitation, loss of appetite, and swelling of the ankles on exertion. He had had bronchitis in 1925 and pleurisy in 1926. The family history contained nothing relevant to his present illness.

On examination he was dyspnoeic, cyanosed (particularly the ears), and anæmic, and had clubbed fingers. There were signs of mitral disease, but no oedema. In the lungs, abdomen, and central nervous system, nothing noteworthy was found. He had "gross pyorrhœa" but no ulceration of mouth or pharynx. Radiography of the chest showed "no unusual opacities." The Wassermann and Kahn reactions were both strongly positive.

¹ Ross, J. M.: Jour. Path. and Bact., 1933, xxxvii., 311.

Progress.—Blood counts from Sept. 12th, 1933, to July 13th, 1934, are summarised in the accompanying Table.

Teeth were extracted on the following dates: August 26th, 1933, Sept. 2nd and 9th, Nov. 4th, 20th, and 25th, and Dec. 2nd, 9th, and 18th, and a good deal of bleeding following each extraction, though it usually

ceased in a day or two. A course of antisyphilitic treatment (neoarsphenamine and bismuth oxychloride) was begun on Sept. 23rd, 1933. On Oct. 16th it is noted that the patient was languid; the spleen was palpable, being 2 in. below costal margin. On Oct. 23rd the liver was still palpable. On Nov. 6th however it was only just palpable, and again on Jan. 9th, 1934, its tip could only just be felt. The liver was not palpable, but there was some enlargement of axillary and inguinal glands, and a little oedema of feet. On Feb. 5th the spleen was again 2 in. below the costal margin, the liver not being palpable. At the beginning of May, 1934, the patient was transferred to St. Mary's Hospital, Sidcup, for convalescence. On July 13th, 1934, he attended Lambeth Hospital for treatment for a carbuncle of the neck, and the blood count taken on that day was the last obtained.

The term "monocyte" as used in the Table includes both the abnormal monocytic forms and the ordinary hyaline forms found in normal blood; the figures in parentheses beneath the percentages of monocytes indicate the number of normal hyaline cells included in each total monocyte count. The abnormal monocyte forms were much larger than the normal hyalines, and the largest encountered measured 43 μ . In Leishman-stained films the cytoplasm was generally of a pale pinkish-blue with rather a "ground-glass" appearance, frequently exhibiting pseudopodia and long, tapering processes; vacuolation of the cytoplasm was seen in many. For the most part the cytoplasm

was finely granular, the granules being of an azure colour and arranged near the nucleus. The shape of the nuclei varied; some were oval, others reniform, and a few were lobulated; all nuclei were rather pale-staining and showed a fine reticular chromatin network. No nucleoli were observed. In many cells, inclusions of erythrocytes and erythrocyte remnants were seen. Almost the whole of these cells were oxidase-negative, the very few which were

Monocytes in blood films.

positive being but faintly so. Supravital staining, using a modified Sabin technique as described by Orr,² gave the characteristics of the monocyte.

My thanks are due to the late Dr. J. A. Braxton Hicks, group pathologist at Lambeth Hospital; to Dr. P. J. Watkin, medical superintendent of the hospital, for his permission to use the clinical records; to Dr. E. N. Allott, group pathologist at Lewisham Hospital, for the blood count of May 4th, 1934, whilst the patient was in St. Mary's Hospital, Sidcup; and to Dr. J. E. McCartney, director of pathological services, L.C.C., for the photomicrograph.

FOREIGN BODY IN THE BLADDER ASSOCIATED WITH PREGNANCY

By R. FARNCOMBE, M.R.C.S. Eng.

OBSTETRIC HOUSE SURGEON, ST. MARY ABBOT'S HOSPITAL, KENSINGTON

THE case here described presents certain points of interest, both obstetrical and urological, in that an attempt to produce abortion by the introduction of slippery elm was followed by normal labour and delivery of a full-term infant, but resulted in considerable damage to the urinary tract.

The patient, a married woman aged 39, was admitted to St. Mary Abbot's Hospital, Kensington, on May 15th, 1935, having been sent by her own doctor with a diagnosis of 34 weeks' pregnancy complicated by carcinoma of the bladder and vagina. She had had six previous normal labours.

On admission she gave a history of dysuria, incontinence of urine, and a blood-stained vaginal discharge for the past six months. Examination showed a 36 weeks' pregnancy, vertex presentation with the head engaging, whilst inspection of the vulva revealed a small amount of granulation tissue surrounding the urinary meatus from which turbid urine was dribbling. Per vaginam the cervix appeared normal, but a hard elongated mass was palpated through the anterior vaginal wall, apparently lying in the urethra and bladder. X ray examination showed a cylindrical foreign body having a thin core of lesser density lying

² Orr, J. W.: THE LANCET, 1933, I., 403.

in the region of the urethra and neck of the bladder. The patient was then further questioned and admitted having introduced a piece of slippery elm, into the womb as she thought, during the third month of pregnancy; she left it in situ thinking that it would be absorbed naturally.

She was seen by Prof. James Young, in consultation with Mr. James Carver, and it was decided, in view of the possibility of damage to the bladder and urethra during labour, to remove it forthwith. The patient, however, went into labour unexpectedly next day; this was

12 13 14 15 16 1
The foreign body after removal (scale in inches).

short and uneventful, and she was delivered of a healthy infant weighing 7 lb. There was no apparent damage to the bladder or urethra, as evidenced by the absence of hæmorrhage, but the patient remained incontinent, the temperature was raised, and the urine very foul, cultures of which grew abundant organisms, chiefly of *Staphylococcus albus*.

On the seventh day Mr. Carver again saw the patient with Prof. Young, and in view of the gross infection of the bladder, removal of the foreign body was decided upon. Suprapubic cystotomy was performed next day, and the foreign body, which was projecting from the urethra into the bladder, was removed. It was found to consist of a thin core of slippery elm, about ten inches in length and one-sixth of an inch in diameter, doubled on itself. Superimposed upon this was a deposit of phosphates forming a solid conical mass approximately $4\frac{1}{2}$ in. in length and $2\frac{1}{2}$ in. in diameter at its greatest width (see Figure). A de Pezzer catheter was inserted into the bladder, and six days later was replaced by a Hamilton Irving box. The wound was healed by the fourteenth day, and on discharge the patient was able to hold her water for two hours.

A subsequent intravenous pyelogram showed marked pyelectasis of both kidneys, and a small bladder having a grossly irregular outline.

I am indebted to Mr. Carver and Prof. Young for permission to report this case.

LOCAL TREATMENT OF VASOMOTOR RHINORRŒA

By A. TUMARKIN, M.B. Liverp., F.R.C.S. Edin.

HON. AURIST, BOOTLE HOSPITAL

At present the most popular forms of local treatment for vasomotor rhinorrhœa seem to be cautery and ionisation. It can hardly be doubted that both of these act by a limited destruction of the mucosa, and though the danger of excessive damage by any single application is probably slight we must remember that patients are liable to require treatment every year and the cumulative effect might eventually be atrophic rhinitis with crust-formation. It is

unfortunate that little has been done to ascertain histologically the extent and duration of the effects of ionisation, but McMahon¹ reports that it produces definite destructive changes in the frontal sinuses mucosa of dogs. Further disadvantages of ionisation are that many patients find it trying; that, even when cocaine is used, it may set up uncontrollable sneezing which dislodges the packing and washes away the electrolyte; and (above all) that there is no means of controlling the coagulative effect, which is apt to be locally irregular.

These considerations have led me during the past few years to experiment with chemical caustics. Various strengths of chromic, lactic, trichloroacetic, and finally carbolic acid were tried, and it became clear that a pure solution of the latter was definitely the best. Before going any further, I must say that I felt all along that such a simple line of treatment must have been tried by many rhinologists. I was not aware however of any systematic investigations until recently when I found a report by Chandler² on identical lines, and I gladly acknowledge his precedence.

The technique of phenolisation is simplicity itself. A small cap of cotton-wool, tightly wound on a Heath probe, is dipped into pure phenol. It is lightly rolled on lint to remove the excess, and then rapidly smeared over the nasal mucosa. A mild reactionary rhinitis usually follows for about a day, but there is no discharge of tissue sloughs. The treatment is painless, only taking a few seconds, and assuming reasonable skill in intranasal applications, the surgeon after a little experience can easily grade the intensity of his application.

Two questions at once arise: how much good does it do the patient, and how much harm does it do the mucosa?

Out of 9 patients treated over a year ago 6 remained free of symptoms for a year or more. One relapsed after about a year's freedom, but was again "cured" by further treatment. One derived benefit for only a few weeks, and another for only a few months. Several recent cases have been more resistant, and I am coming to the conclusion that further experience in selecting cases is desirable. In particular, I believe that this line of treatment is better suited to the cases of the chronic than of the acute seasonal type.

The second question could clearly only be answered by animal experiment, and I am indebted to Prof. C. E. Walker for his advice and help in experiments on rabbits in the histology department in the University of Liverpool. Phenol was applied to the nasal and also to the tracheal mucosa, and the animals were killed and examined after varying intervals. The results are precisely what one would expect. For one or two weeks the mucosa is covered by tough coagulum. The submucosa shows vascular engorgement and round-cell infiltration. After a time resolution occurs. Nevertheless in certain minute areas necrosis has extended to the basement membrane, and so continuity can only be restored by scar tissue. Of course the technical difficulties of applying the acid to the delicate tracheal mucosa via a miniature bronchoscope were formidable. It is not unfair to assume that the more robust and accessible human mucosa would come to no harm from this application in careful hands. Certainly it will compare favourably in that respect with other forms of treatment.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF PSYCHIATRY

At a meeting of this section on Oct. 8th Dr. H. J. NORMAN gave his presidential address on

Psychiatric Digressions

Laying stress on such matters as personal predilection dictated or as seemed to require discussion.

The strict meaning of psychiatry, he continued, was "the treatment of mental disease," but the word had come to have wider implications and is used synonymously with psychological medicine. It was the section of medicine which dealt with the causes, symptomatology, course, and treatment of mental disorders. Even this did not give a clear indication of what the subject embraces or of what led up to an adequate comprehension of it. Preliminary to it there was the study of psychology and indeed of philosophy. The neglect of the study of these had often been regretted; it would have been still more regrettable but for the fact that so much of it was a waste of time, arid, and unfruitful. With the growth of knowledge, however, there had he thought been a gradual change in this respect, and it was to be hoped that there would soon be a more or less general consensus of opinion on the essentials which the students should acquire. Prophylaxis was of great importance. It had long been apparent that of the causative factors of mental disorder the one of pre-eminent importance was hereditary predisposition.¹ Even where an exogenous factor—e.g., alcohol—appeared to be predominant it was nevertheless often only an exciting one. This aspect of the matter was, therefore, one of eugenics.

PROPHYLAXIS AND TREATMENT

Unfortunately, however, when it was suggested that manifest psychotics or defectives should not be allowed to breed, many loud cries of dissent were heard. It was true that this predisposition was negative in character but the same thing might be said of many diseases. It was the lowering of resistance which was important there also; and if resistance could be increased by any means—for example, in the common cold or in phthisis—the pathogenic factor might be successfully resisted. So, perchance, with the psychoses. It might be taken for granted that psychotic people would continue to be born. The realisation that there was a predisposition was of value because it might be possible to arrange that the individual would so order his life as to avoid those factors which are fraught with greater danger to him than to someone more stable. The nervous child might be guarded against overwork and insomnia when he worried unduly over school routine. In recurrent cases the attacks might be minimised or shortened. Some day there would perhaps be more legal restrictions upon the chronic alcoholic so that he might be prevented from drinking himself into dementia and his family to destitution. Treatment was of course the culmination of their efforts and of their investigations; but this itself was dependent on diagnosis,

on the recognition as far as possible of the ætiological factors, on the existence of adequate facilities, and on the willingness of the patient to undergo or of his friends to consent to what was requisite.

Undoubtedly much improvement had taken place; but there had not been a coincident variation in the recovery-rate. It was hardly fair to blame the mental hospitals for this—while they were still apt to be regarded as a last resort to which patients were sent when everything else had failed. Even in reaching such a conclusion as this it was only just to consider the results of treatment in general medicine and in surgery. There were many chronic diseases in which treatment could only be palliative; but these diseases were not, in many instances, so socially disabling as were the psychoses, or they were more fatal. A point to be remembered also was that statistics as to cures—or of failures—were more readily accessible in regard to mental hospitals; so the critics had their materials more ready to hand. General hospitals were as a rule more fortunate in this respect; and it was but human to lay stress on the successes and to minimise the failures. It would be a great comfort in medicine if it was known in even a good proportion of successful cases how actually the cure was effected. In the gradual emergence of medicine from an art into a science it might be hoped that the *post hoc* fallacy would become a thing of the past and that it would be possible to add *propter hoc* with complete veracity—though not, doubtless, with greater assurance! The treatment of general paralysis might legitimately inspire hope not only so far as that condition was concerned but in some others which had so far proved refractory. For example, it might be possible some day to readjust the balance—glandular, perchance—in manic-depressive disorders, or to discern what was the actual degenerative change in the schizophrenic group.

Dr. Norman then discussed the relative importance of psychology and of the philosophic aspect in general. The decision to which of the philosophic schools with their varying, often contradictory, opinions one gave allegiance seemed for the most part to be a matter of temperament. His own leanings were towards empiricism, which had been defined in the "Encyclopædia Britannica" as "the theory that all knowledge is derived from sense experience. It is opposed to all forms of intuitionism, and holds that the mind is originally an absolute blank (*tabula rasa*), on which, as it were, sense-given impressions are mechanically recorded, without any action on the part of the mind." He discussed at some length the grounds on which this philosophy was based and concluded that given the conditioned reflex and all the inferences made possible thereby, a cerebral mechanism could be constructed which was surely adequate for all the intellectual products of a Shakespeare, a Goethe, a Dante, or even of a Bernard Shaw. In the same way that the process of evolution demonstrates the gradual building up, so did the devolutionary changes show the absolute dependence of mind upon organic structures. Day by day they had to watch the fearsome experiments which nature performed on suffering humanity. These demonstrated only too clearly the gradual and final moral, intellectual, and emotional degradation which occurred if the process was not checked. Other lines of study had their own importance—for example, the application

¹ Dr. J. C. Prichard was quoted by Samuel Tuke in his introduction to Jacob's On Hospitals for the Insane as long ago as 1811 as saying: "Mental derangement, considered generally, or with respect to the aggregate number of cases, may be looked upon rather as a congenital imperfection, than as a disease resulting from external impressions."

of our knowledge of mental disorders to biography and history; to the borderland of insanity where the maddoids, the eccentrics, some of the sexual perverts, and a good many criminals were to be found, and on the outskirts of which the more fanatical devotees of strange cults existed; to the question of the neuropathic constitution of so many men of genius; to the social aspect and the influence of the neuropath in bringing about revolutions and wars; and in endeavouring to counteract the misconceptions which still exist among the public with regard to insanity so that more reasoned, more dispassionate views may prevail. He dealt fully with some of these aspects, notably with popular misconceptions or fallacies regarding mental disorders, in the past and in the present. It would be idle to maintain that there was not room for improvement in mental hospitals, but there were no reasonable grounds for the sweeping accusations that continued to be made. These were unjust to those who had charge of the patients and distressing to relatives and friends. It was not the good faith of the critics but their knowledge which was at fault, and this led to exaggeration and distortion in their statements.

PROBLEMS OF DETENTION

Conditions in asylums in the past were certainly bad. The testimony of reliable persons made that clear, as did also the official reports of the time. But many of the writers who described them were romancers who saw to it that their tales lost nothing in the telling, and because they were by nature imaginative, could hardly avoid distortion and misrepresentation. In addition they might have, perhaps unwittingly, allowed themselves to give undue weight to tainted evidence, especially with regard to the matter of illegal detention. The speaker admitted that after hearing some of the testimony in the law courts he would at times prefer to accept that of the patient—even of the certified one. But there were those whose preference was for the allegations of the insane, or, at the least, of the half-mad, if their statements are adverse; and these same persons would be justifiably annoyed if such allegations were accepted against themselves in a court of law.

Dr. Norman quoted some comments on "the horrors of certification" and "the scandal of the Urgency Order" from the modern daily press. He was not concerned to discuss specifically such allegations—though that would be an easy matter—but with the general tone and the attitude which they typified. It was all so simple to these self-appointed critics. Lacking practical knowledge of what it meant to have to deal, day in, day out, with the mentally disordered, they could not begin to appreciate the difficult problems which had to be faced. For example, when could constant and vigilant supervision be relaxed in the case of the suicidal patient; when should he be allowed out alone on parole; or at what stage in his progress towards recovery was it advisable to suggest that a patient should be discharged from certificates? Again, what was to be done with the voluntary patient who gave notice of his intention to leave and of whom it was felt that he might become a danger to himself or to others. A patient might be plausible, lucid, and might argue rationally—his premises being granted—and yet might attack his companions like a fury when released from control. There was also the person who had recovered sufficiently to be discharged but had never realised adequately that he has had an attack of mental disorder. His cloudy recollection might be of the struggles associated with

such things as feeding, bathing, and indeed with many events in which his negativism had been overcome only by considerable effort. This, which was a matter of daily experience to nurses, was understood by few besides them. There was, too, the patient who always had a grudge and a grievance, who moved from one hospital to another, but was always disgruntled. It is not in mental hospitals alone that this type was to be found; every boarding-house and hotel knew it.

Such patients formed, fortunately, a very small percentage of the total, but there seemed every likelihood, however, of that proportion being maintained. It had to be remembered that the most difficult, troublesome, exigent, and querulous individuals in the community were relegated to the mental hospitals—frequently after they have exhausted the patience of their relatives and also when they had already been subjected to treatment elsewhere. The lay press exercised great power and influence, for the most part wisely and honourably. Dr. Norman pleaded, therefore, for a wiser discretion in the attitude which editors adopt in these matters and a more careful sifting of the evidence presented to them, otherwise they might do more harm than good. By inspiring fear of mental hospitals in patients and friends, they might cause delay in patients being placed under care, and they added to the anxieties—already great in many cases—of the relatives.

Dr. Norman quoted extracts from various sources, including the Report of the Royal Commission on Lunacy and Mental Disorder (1926), as evidence that there is no foundation to justify allegations of improper detention or ill-usage in mental hospitals to-day, and from an article of his own published 22 years ago entitled "The Brighter Side of Mental Hospital Life" to show that the mental hospital is not a gloomy place. One fact noted by Dr. Donald Gregg (1932) which had always appealed to him (he had very often used it for the encouragement of patients) was that in the majority of cases unhappiness was a symptom of favourable prognostic value. It was still held by many that a patient's mental condition was made worse, or even that insanity is caused, by association with other patients; and it was even said that members of the staff of a mental hospital were influenced in some sinister way and became "mental cases." If they did, the numbers were not disproportionate to the incidence in other occupations, and even if insanity did occur frequently in these staffs a reason might be sought, not in "communicated" insanity, but in the arduous and worrying nature of the work. Actually it would appear to be a difficult matter to cause a psychotic condition. It was quite a common experience even nowadays to have to discuss this aspect of the matter with relatives—even with doctors—who regarded it as not only a possibility but, indeed, as a probability. Just about a hundred years ago an enlightened alienist, Dr. Jacobi of Siegburg, affirmed "that among six hundred cases he had never witnessed one in which the patient sustained any material injury from his residence in the establishment . . . or from any influence exercised upon him by the other patients." From a more considerable experience Dr. Norman could confirm Dr. Jacobi's conclusions. The contrary might indeed be asserted with considerable confidence, possibly because man was a gregarious animal. Even melancholics sometimes profited by an awakening of interests other than in their own morbid state, and the introspective type which may well be described as the "malade imaginaire" might also benefit therefrom.

HISTORICAL APPLICATION

It would be found, Dr. Norman went on to say, that the application of psychiatric methods to the study of biography and of history had a more than academic interest. History might not repeat itself; but the course of events might nevertheless be predicated with some confidence if the constitution and the circumstances of an individual were known.

The manic-depressive, the melancholic, the paranoiac, the alcoholic, the epileptic, may possibly bring much trouble to themselves or cause it to others when they have freedom of action or when they are encouraged to give rein to their morbid proclivities. It is bad enough when they are merely subjects; but magnify their opportunities by giving them unlimited power and the results may be disastrous. Not always so, however, for, as we see the patient in a hypo-manic phase writing or talking brilliantly, or carrying through business transactions, so we read of the amazing careers of kings, conquerors, great statesmen and dictators, who lived on the borderline of insanity or who actually were at times mentally disordered, but, who were able, for the most part, to do great and successful work: Alexander the Great, looking for fresh worlds to conquer and dying of alcoholic excess after having "emptied ten times the goblet of Hercules," Julius Cæsar, Richelieu, Napoleon, Peter the Great, Charles V., Frederick the Great, Clive, who twice attempted his life in his early years and eventually committed suicide at the age of 49. But consider the other side of the picture and contemplate the careers of Nero, of Heliogabalus, of Ivan the Terrible, of Jean Paul Marat, King George III. suffered from manic-depressive insanity and Pitt (Earl of Chatham) had recurrent attacks of mental disorder; what influence did this have on our foreign policy, remembering that it was the epoch when we lost the American Colonies? Wars, "holy" as well as other kinds, have been brought about or incited by fanatics playing on the emotions of the populace. When we look abroad in the world we can still appreciate how applicable is the saying of Dr. Johnson—"As a madman is apt to think himself grown suddenly great, so he that grows suddenly great is apt to borrow a little from the madman." There are at the present time individuals holding prominent positions and influencing the destinies of countries, who are known to be unstable mentally or who have actually had attacks of mental disorder. We know that after recovery from an attack, or in intervals between the disordered phases, a person can be as capable as ever; but it seems an undue risk, for the individual and for the State, to place too great a responsibility, with all its anxieties and worries, upon the shoulders of such a one.

Bearing these facts in mind, is it unreasonable to hope that there may be safeguards so that they shall not occur in the future? Will it ever be possible to limit the scope of action of such individuals, especially if they are known to be unstable? It seems an idle dream so long as we cannot set our houses in order in philosophy, in religion, in art, in politics, or in medicine. Always contest and controversy—so that we have to save our conscience by saying that war is necessary, even beneficial, and making our motto not charity and long-suffering but "I come not to send peace, but a sword," or "War is a terrible trade; but in the cause that is righteous, sweet is the smell of powder."

Instead of man considering himself as so wonderful "a piece of work" it might be better if he were trained more along materialistic lines; and rather than say, half-heartedly, that he is a miserable sinner—which only the melancholics really believe themselves to be—admit that the human mechanism is a fallible and delicate one which a fever, some glandular change, disorder in the cerebral circulation, can throw out of gear; and that if "great wits are sure to madness near allied," the small ones also are only divided from it by "thin partitions."

Indeed it is "a mad world, my Masters." Apropos— one of my patients recently handed me a cutting from the *Times* with this passage underlined—"As I look at the world of 1935 it seems to me to have gone mad, or, as an alternative, that I must have gone mad myself." It looks as if there may be a great future for psychiatry!

In this connexion there is an interesting movement initiated by the Netherlands Medical Association under the title of the Committee for War-prophylaxis. In a communication which I have received on the subject the following passage occurs—"The psychiatrists should try to strength the opposition against war, . . . Besides the activity which each of them may develop by himself or together with his colleagues within his own country, the psychiatrists can, by international co-operation, attempt to bring the nations and their leaders to a realisation of fact; they can enlighten them on the psychic mechanisms which cause war."

This may at the present time, Dr. Norman concluded, seem rather a forlorn hope, but it is one with which I gladly associate myself and to which, I trust, many will give their benison.

INSTITUTE OF MEDICAL PSYCHOLOGY

Prof. C. G. JUNG visited the institute last week to give five seminars on

Fundamental Psychological Conceptions

His first lecture dealt with his view of the structure of the mind: the nature of consciousness and unconsciousness and the ecto- and endopsychical functions. He said that the four ectopsychical functions consist of sensation, feeling, thinking, and intuition, and the endopsychical functions consist of memory, the subjective components of conscious functions, the affects, and the invasions. The ectopsychical functions he has dealt with in great detail in his "Psychological Types"; the endopsychical are not so familiar. He explained memory as the function that links a man up with the things that have faded out of consciousness, that have become subliminal or repressed. The subjective components of conscious functions determine the instinctive reactions of a person to other persons or situations; they are the emotional contents that play such an important part in projection and transference. The affects are not really functions but events, emotions that possess the man and of which he may control the expression but not the existence. In invasion the unconscious has full control: it can break into the conscious condition and the man is then beside himself and not responsible for his behaviour.

The discussion brought out some interesting distinctions between emotions and feelings, principally the fact that emotions have a definite physiological counterpart—the flush of anger, the heightened pulse-rate, or the psycho-galvanometric response. Prof. Jung also developed his view that feeling is a rational function, a view which is perhaps peculiarly difficult for Englishmen to appreciate. It is, he says, the function by which we assign values to things; it is quite independent of thinking and may be antagonistic to it. Just as there may be abstract thinking, so there can be abstract feeling: values may be as abstract as ideas. A man may adapt himself to life by means of either one of these functions, but never by both equally; one of them will always be inferior, relatively undifferentiated, and ultimately uncontrolled.

At the beginning of the second evening Prof. Jung began to deal with the structure of those depths of the unconscious mind which lie below the personal unconscious, or subconscious. The contents of the "collective unconscious" are mythological, archaic, archetypes which are common to mankind in general. An uneducated negro in the Southern States will dream of a man crucified on a wheel, the Ixion of Greek legend, the ancient sacrifice to the sun-god,

A schizophrenic patient will have a vision which, stage by stage and even word by word, is identical with the account of another vision in an Egyptian papyrus. This is Prof. Jung's chief interest, and he has performed an enormous amount of research, with the assistance of expert philologists and archaeologists, into the myths of such widely separated civilisations as the ancient Greek, Babylonian, Chinese, and Aztec, and into the legends and religious beliefs of many uncivilised peoples such as the Pueblo Indians of Mexico and the Bantu tribes of East Africa. The rest of the second lecture was chiefly devoted to an exposition of the word association test as Prof. Jung uses it both in private practice and—strange procedure to English minds—to determine the guilt or innocence of persons accused of crime.

DREAM ANALYSIS

In the third lecture, on dream analysis, he managed to compress into his comments on a consecutive series of dreams by one patient a whole text-book on the practical use of dreams in psychotherapy. His first rule is common to all diagnosis: that prejudice is fatal. When a patient relates a dream the doctor must put aside all that he knows about the patient or the art of dream interpretation in order to deal with an entirely new problem. Only by finding out what each symbol means to the patient can he venture to attribute a meaning to the dream. Therefore he handles it as if it were a Greek or Sanskrit text and applies ordinary philological methods. The dream, he says, does not conceal; merely, people do not understand it. Just as the philologist, applying the principles of amplification, seeks the parallel application of an unknown word in other texts, so Prof. Jung inquires from the patient what the symbols of the dream mean to him. A patient dreams of water: he may associate it with greenness, with H_2O , or with suicide. In any event, his association will indicate the "tissue" in which the word or picture is embedded. Secondly, Prof. Jung insists that every dream has a history before it and will have a history after it; it is part of a continuous tissue, a long film, and one dream is a single observation through the time-slit. Nevertheless, there is, he says, a particular class of dream which the analyst may venture to interpret without knowledge of the patient's personal associations, simply because the dream is impersonal: it comes from the collective or impersonal unconscious which is common to all mankind and therefore all mankind are qualified to interpret it, because they will attach the same meaning to its symbols. Such dreams are called by savages "great dreams," as opposed to ordinary dreams, about which savages feel much the same indifference as do materially minded civilised people. These "great dreams" have a peculiar compulsive quality of their own; this quality not only imposes itself upon the patient but also upon the physician and upon anybody else who hears of the dream. Its symbols are archetypes of mythology—serpents, wells, daggers, bowls, monstrous animals, heroes.

Prof. Jung is developing the theory that these mythological dreams are related to the organic structure of the body. He has certain reasons for thinking that the serpent often represents the cerebro-spinal system, especially the medulla and spinal cord. The crab, being invertebrate, represents chiefly the abdominal sympathetic and parasympathetic systems. He proceeded to develop the theme, relating the dream of a young man which depicted a dark chamber containing a well, below the cathedral in the city of Toledo; the chamber was inhabited by a serpent and

contained a dagger. These symbols he said, can be paralleled in practically every repository of legend and stand for the task which every man has to descend into and subdue his inherited and parental components.

TRANSFERENCE

He was not, unfortunately, able to complete his analysis of this dream, and it will probably long remain for many of his hearers a teasing, unsolved riddle. In response to urgent requests, he decided to substitute a lecture on transference and its treatment, which was a most practical piece of instruction. The problem of transference is inseparable from psychotherapy; Prof. Jung gave his audience a rare insight into it. He defined it as a special case of projection; whereas projection may carry over subjective contents into an inanimate object, transference is a projection on another person. Like any projection, it is involuntary—"You find it." The emotional contents that are projected have a compulsory influence upon the subject, for the emotion is not detachable from him. There is a link, an elastic string, which no will-power can break. Even if the doctor is entirely detached from the patient's emotional processes, the transference must have a certain effect; it is his duty to some extent to accept and mirror the transference. This is why Prof. Jung always sits in front of his patients and talks to them as to normal human beings, reacting humanly to their emotions. When the patient's projection is identical with contents in the doctor's mind which he also projects, there is a counter-transference and the end of the analysis is usually disaster. This is why analysts ought to be analysed, even as the Pope has a father confessor, so that there will be no blind spots in their minds through which a patient—the most cunning of beings—can take possession of their unconscious emotions and cause what Prof. Jung calls personal contamination through mutual unconsciousness.

Transference, according to Prof. Jung, is not by any means exclusively erotic, he says: all activated contents of the unconscious that can be projected on to a person may be the contents of transference. The intensity of the transference relationship is always equivalent to the importance of its content to the subject, and if he can overcome it, the amount of energy that has been wasted in the projection is available for useful conscious activity. Transference is by no means love; on the contrary, it is a misuse of love. It may be set up at first sight, but is usually only established through analysis. It is then often caused through a difficulty of emotional relationship between the doctor and the patient. If they cannot get on together as human beings, then spurious and compulsive feeling comes in as a compensatory mechanism, an attempt of the unconscious to bridge the gap on a lower level. It is a measure of lack of sympathy, not of the strength of it. The worst transferences occur in patients who are shut up in themselves and resist human relationships.

When a transference is in existence, the doctor will often be warned by a compensatory dream or phantasy that he is taking a false attitude towards his patient. Prof. Jung stressed the interesting and unusual view that transference is by no means a necessary or even a desirable part of analysis, but an epiphenomenon which is nothing but a hindrance and should not exist, which should if possible be avoided, and which at best serves only as a warning that things ought to be better managed. Incidentally, Prof. Jung in this lecture made a vigorous defence of his absorption with mythology. He declared

that he would never have worked out the meaning of mythological symbolism if he had not been terribly pestered with transference. His endeavour to solve it, he said, took him into this field of research, and he has already been able to gain knowledge of incalculable value to every practising psychotherapist.

ACTIVE IMAGINATION

Prof. Jung had intended to devote the fifth seminar to the subject of active imagination, but as he decided to interpolate the lecture on transference, he could only find time for a short survey of the subject in answer to a question. Active imagination, he explained, is a method of investigation which cannot be carried out by all patients, but which in those specially gifted is a much more powerful, controllable, and creative method of investigating psychic contents than word association or even dream analysis. It is

a process of direct fantasy by which the patient can enter, actively and not passively, into his unconscious mind. The key which unlocks the door is probably different for each patient, and may require careful search. Some patients enter by means of drawing or painting symbolical pictures; others by means of descriptive writing; others may look at a picture and discover that they are part of it and are following a road, as did Alice through the Looking-glass, that leads through it into unportrayed country. The process is essentially creative whatever form it takes and has nothing to do with passive day-dreaming. Its results are often intensely interesting and valuable to the patient. The activity affords an almost immediate sublimation of the energy which has hitherto expressed itself in neurotic symptoms, and the patient has a good prospect of a rich reward in self-development and integration.

REVIEWS AND NOTICES OF BOOKS

Bacteria in Relation to the Milk Supply

By C. H. CHALMERS, B.Sc., N.D.A., the University, Leeds. London: Edward Arnold and Co. 1935. Pp. 192. 6s.

THE author has incorporated into small space most of the essential information concerned with the bacteriology of raw and heated milk. The routine bacteriological examination of milk and water, including the object of such examinations, the description of various technical procedures, the advantages and disadvantages of the different methods noted, and the interpretation of results are clearly explained. Taints and abnormal conditions in milk, the isolation and identification of organisms from milk, and the control of the dairy plant are then discussed, and in the remainder of the book the general methods of bacteriological technique are described; these include the preparation of culture media used in dairy bacteriology and the use of stains and microscopes. The Ministry of Health milk standards are also noted.

The book is so arranged as to be of considerable assistance to the trained bacteriologist suddenly faced with dairy bacteriological problems, whilst the untrained laboratory worker, the dairy worker, and the farmer can all gain practical guidance in their own particular fields. The chapter on taints and abnormal conditions includes a description of the contaminants of milk, the manner in which they may alter the milk, the identification of such organisms, their usual source, and method of avoidance. Without going too deeply into the realms of determinative bacteriology, sufficient information is given to enable a tentative identification to be carried out, following which recourse can be made to the appropriate literature. The condensation of this hitherto scattered information into a single chapter is of particular value to those concerned with the bacteriology of dairying.

Mr. Chalmers has performed an extremely useful service in thus assembling all the essential information regarding the bacteriology of milk. The book is attractively set out and well printed, and the illustrations are clearly reproduced.

Science and Religion

By N. BISHOP HARMAN, M.A., M.B., B.Ch. Cantab., F.R.C.S. London: George Allen and Unwin Ltd. 1935. Pp. 175. 5s.

Mr. Bishop Harman, adding another to the many books which have been written on the relations of

science and religion, finds no difficulty in their harmonious coöperation in the satisfaction of a man's soul. A religious man takes pleasure in contemplating the goodness of God and likes when he is by himself to let his mind range round mysteries which are at the moment beyond him, but which he hopes may come within his comprehension. A scientific man delights in the order of nature and lets his imagination run on what is just round the corner rather than what is in sight. One is much the same as the other, and a scientific man is driven to be religious more certainly than a religious man is attracted to science. To neither is dogmatic theology essential or material. We doubt whether the thesis that "religion promises its disciples certain boons" could be maintained as a general proposition, and we wonder who is the "James Hinton" of p. 127 who wrote a book entitled "The Mystery of Pain."

The subject discussed in this book maintains its interest for many people in whose youth the conflict between religion and science was a live issue, and it is to them rather than to the younger generation that it will make an appeal.

The Nervous Patient

By CHARLES PHILLIPS EMERSON, M.D., Research Professor of Medicine, Indiana University, Indianapolis. London and Philadelphia: J. B. Lippincott Company. 1935. Pp. 453. 18s.

THIS useful work has the advantages and disadvantages of having been written, not by a psychiatrist, but by a physician interested in the psychological aspect of his patients' illnesses. Dr. Emerson, after 20 years as professor of internal medicine, has come to the conclusion that none but the internist can "evaluate those elements which the patient's disturbed personality injects into the clinical pictures of organic diseases; he alone can recognise those almost exact imitations of these same organic diseases which have their origin in the emotional life of the patient." But for much of his knowledge of neurotic mechanisms and ways of dealing with them Prof. Emerson seems to be dependent more on the literature of psychiatry than on a large personal experience. His best chapters are those in which he gives straightforward accounts of the symptoms, diagnosis, and treatment of physical diseases, accompanied by reminders and discussions of the psychological factors that may affect the system in question. There is a falling off in the second half of the book,

which deals with disorders of sleep and sex, the development of personality, and the varieties of mental disorder. It is, however, clear that Prof. Emerson has not aimed at any profound study of the topics covered, but rather at a mildly critical survey that would be of use in practice. The book as a whole is a sensible and trustworthy guide for the general practitioner who desires to pay regard to an often overlooked but very important part of all illness and treatment.

Cunningham's Manual of Practical Anatomy

Ninth edition. Revised by J. C. BRASH, Professor of Anatomy, University of Edinburgh; and E. B. JAMIESON, Lecturer on Anatomy in the University. London: Humphrey Milford, Oxford University Press. 1935. Three vols. Pp. 1467. 12s. 6d. per vol.

It is a pleasure to see a new edition of "small Cunningham," and to see in it the terminology now definitely adopted by the Anatomical Society of Great Britain and Ireland. The original author passed it through its first four editions, after which Prof. Arthur Robinson carried it on for nearly a quarter of a century. This is the first issue under the present editors, who may safely lay aside the misgivings of which they speak in their preface. They have produced an excellent work, in which any changes made have been in the direction of guiding the student's mind towards the clinical value and application of his work. The volumes have been reduced in size, although several new figures have been added, and an introductory chapter containing general information and directions for the dissector. The work will easily maintain its premier position.

Modern Methods of Feeding in Infancy and Childhood

Fifth edition. Revised by DONALD PATERSON, B.A., M.D. Edin., F.R.C.P. Lond., Physician for Diseases of Children, Westminster Hospital; Physician, Hospital for Sick Children, Great Ormond-street; and J. FOREST SMITH, F.R.C.P. Lond., Physician, St. Thomas's Hospital. London: Constable and Co., Ltd. 1935. Pp. 213. 7s. 6d.

THIS excellent little volume has now become well recognised as a simple and straightforward handbook of infant feeding. The fifth edition differs little from the fourth, which appeared only last year. Breast-feeding has been placed in the forefront to emphasise its importance, and the section on diarrhoea in the breast-fed infant has been rewritten. Several of the tables have been brought up to date and reset, and reference is made to recent work on nutritional anaemia, the occurrence of undulant fever in this country, and the requisites of a "safe" milk-supply. The book is attractively printed, and is designed to be comprehensible to the intelligent laywoman. It should continue to be popular amongst all those concerned with the rational feeding of infants and children.

Chirurgie de l'œsophage

By RAYMOND GRÉGOIRE, Professeur à la Faculté de Médecine de Paris. Paris: Masson et Cie. 1935. Pp. 179. Fr. 35.

In this book the present position of the surgery of the œsophagus is set forth with clearness and restraint. This is particularly true of the chapter on carcinoma. No exaggerated claims are made for

radiation treatment and it is freely recognised that the problems of operative removal are not yet solved. The few successes which have occurred, whilst they establish the ultimate possibility of the procedure, are regarded as due to a happy combination of circumstances not under the control of the surgeon. Moreover, the author points out that dysphagia is usually a late symptom in the evolution of the disease. No less than seven times has he exposed the thoracic œsophagus with a view to resect a growth, only to find in each case that the extension to surrounding parts was so great as to cause him to abandon his intention. The accounts of other diseases of the œsophagus—diverticulum, peptic ulcer, and cardiac achalasia—are extremely good and the sources of information are given in admirable bibliographies. The relation of the sympathetic to cardio-spasm is not mentioned, but admittedly this new surgery is not yet sufficiently established for any reliable deductions to be made.

Clinical Atlas of Blood Diseases

Third edition. By A. PINER, M.D., M.R.C.P., Assistant Physician, St. Mary's Hospital for Women and Children; Physician, St. Pancras Dispensary; and STANLEY WYARD, M.D., M.R.C.P., Physician, the Cancer Hospital, and Princess Beatrice Hospital. London: J. and A. Churchill Ltd. 1935. Pp. 110. 12s. 6d.

A THIRD edition of this clinical atlas suggests that the book is appreciated by students and practitioners. As the authors state in their preface "the progress of hæmatology since the publication of the last edition has been in the direction of clinical rather than morphological elaboration. For this reason no new plates have been added, but the whole of the text has been revised." In the course of the revision, however, no mention is made of the important work done both in this country and in America on erythroblastosis foetalis, showing the probable relationship between icterus gravis neonatorum, hydrops foetalis, and anaemia of the new-born. An account of the extremely characteristic Donath Landsteiner reaction in paroxysmal hæmoglobinuria might be of more help in the diagnosis of this condition than a coloured print of the blood film, which is in no way peculiar. The section on abnormalities affecting the white cells contains an account of agranulocytosis and mention is made of monocytic leukemia. The glossary has been brought up to date by the inclusion of such terms as achrestic anaemia. J. R. Ford's illustrations are beautiful and accurate.

Crook Frightfulness

By A Victim. Birmingham: Moody Brothers. 1935. Pp. 196. 7s. 6d.

THIS painful narrative is an account of the persecution to which its author believes himself to have been subjected since 1922 by powerful and ubiquitous enemies. He tells his story vividly and is passionately convinced of its truth. Few such detailed first-hand accounts as this have been published. Much of the book is taken up with repetition of the insults and mysterious interference which the author noticed wherever he went, so that he was driven, as he says, "around the circuit of the globe in my efforts to escape." Although the narrative appears to have been edited, it is an interesting document, especially for the psychiatrist.

THE LANCET

LONDON: SATURDAY, OCTOBER 12, 1935

HEALTH AND DISEASE ON PAPER

WHEN it comes to the preservation of his own health and happiness is the doctor in a better position than the ignorant layman? In an ideal society would everybody go through the whole medical curriculum so as to have a fair working knowledge of health and disease as they affect himself and his friends? Or if not, would the Utopians be content with teaching everyone elementary biology, first aid, and home nursing? The question seems fanciful, but the medical profession may reasonably be expected to hold considered views on *What Every Intelligent Layman Ought to Know*. Sir HENRY BRACKENBURY has lately acted on some of his own opinions by producing a book, "Patient and Doctor,"¹ which is primarily an attempt to make its non-medical readers coöperate more usefully with their advisers. His object is not so much to sow the seeds of medical wisdom as to make the ground receptive for such seeds as practitioners may later see fit to scatter. Dr. HARRY ROBERTS on the other hand has been far more ambitious. He believes that the ideal layman would know a great deal about his body and mind long before the doctor's car was heard coming up the drive; and the scope of his "Everyman in Health and in Sickness"² is such that it may be said not only to prepare the ground but also to sow a good representative collection of seeds and show the reader how to do the reaping. One critic may say that if all this is to be bought for 12s. 6d. there will be nothing left for the doctor to do except to bless the crops and attend the harvest festival. Another will point out that neither farming nor medicine can be learnt out of books, and that the chief effect will be to make the layman more uncomfortable about himself and his affairs and more prone to take his troubles (complicated by a little knowledge) to the expert. Whichever is right we believe Dr. ROBERTS should have credit for attempting such an immense task and for partial success on an important scale. To be fair the critic should say to himself: If I do not like this book what sort of book (if any) would I have tried to write myself? What in fact should the intelligent layman know, and how, under the circumstances of the present day, should he get to know it?

Our own attitude towards "health education" was declared some years ago in a leading article³ which quoted respectfully some very pungent

sayings by certain leaders of the profession but added: "Is it true that medicine has nothing to offer the public beyond St. Paul's counsel of temperance? Faced with the distresses of modern society, must we remain silent about fresh air, fresh food, and flies? . . . Must we really leave the slums to their unconscious health for fear a little enlightenment may make them over-anxious?" Dr. ROBERTS and his unnamed collaborators have done much more than write about air, food, and flies—so much more, indeed, that they offer great scope for disagreement as well as for praise. In our opinion their book would be better if it were not so long and comprehensive, and though the careful reader will feel admiration for so lucid an account of human natural history he will like some parts much better than others. In describing the anatomy and physiology of man a lavish use is made of technical terms, and there are several sections of the book—notably one on metabolism and food utilisation—whose perusal ought to bring the reader up to M.B. standard at least. "We must now see," says the author cheerfully, "how the body deals with the amino-acids which it absorbs from the digestion of protein." But the average reader is not going to admit a necessity so painful, and he will certainly do better to browse quietly in the chapters on the mind, on the upbringing of children, on birth control, on danger signals, and on nursing the sick. Unfortunately, being human, he may find himself under a morbid compulsion to read also about the endocrine system and its disorders or about the other diseases described at greater or less length in the later part of the work. There are a few statements in these sections to which we may take exception: for example, is it true to say that hare-lip is hereditary; that tuberculous meningitis is always fatal; that a child with measles is best treated in a fever hospital; that boracic fomentations should be used for boils; or that infantile paralysis is "common" in children of two or three years old? There is also food for needless anxiety in remarks like "migraine is a condition which some think is related to epilepsy." But the fault, if there is one, lies not so much in the framing of an occasional alarming or doubtful sentence as in the whole attempt to tell the public about disease. There are many minor disorders with which everyone should be familiar, and most of them are described very well in Dr. ROBERTS's compilation. But when more serious or incurable illness is in question the patient and his family should learn their facts from the family doctor and not from the book-shelf. According to this view the ordinary home does not require a work of reference containing accounts of disseminated sclerosis, dementia præcox, or auricular fibrillation, and the present work is least attractive where it most closely approaches the old style of popular medical encyclopædia whose motto was "everyman his own doctor." The authors would have done well perhaps to bear in mind more often the (probably spurious) Arab proverb: It is good to speak the truth; but it is better to *know* the truth and speak about date-stones.

¹ Reviewed in THE LANCET, Sept. 28th, pp. 722 and 729.

² Everyman in Health and in Sickness. By Dr. Harry Roberts and Others. London: J. M. Dent and Sons, Ltd. 1935. Pp. 739. 12s. 6d.

³ THE LANCET, 1931, I., 357.

So much for the informative side of the new volume. But that is only one side; for the writers naturally and rightly set out to be persuasive as well as instructive, and their aim—their propagandist aim—is to make their fellows healthier and happier. Propaganda has a bad name; nor do we want (as Sir KINGSLEY WOOD says in his message commending the present Health Week), “a nation of people who are forever thinking about their health.” It is also true, as Lord HORDER has pointed out, that maxims drawn up for guidance in personal hygiene should embody general principles and avoid particulars; “since they go to all and sundry, to the young and to the old, to the fat and to the lean, to the blonde and to the brunette, to the tall and to the short, to the phlegmatic and to the sanguine, to the asthenic and to the sthenic.”⁴ At the same time none of us would lightly surrender the knowledge of ourselves and our maintenance which we have gained from our medical training and experience, and we can only wish Dr. ROBERTS well in his attempt to transfer something of his own knowledge, acquired in a lifetime of general practice, to those who very obviously stand in need of it. We would go further. If there are chapters in his book which would make a very suitable revision course for the student entering his final examination there are also chapters—and many of them—which would be more than useful to the successful student who is shortly to apply his knowledge to practice: they would draw together much that may be stored in his mind but has not achieved unity. Those whose eyes are looking chiefly for occasion to differ will find much that will stand in the way of a proper appreciation of Dr. ROBERTS’s volume—from the photographic illustrations onwards. It does not take long to discover that some of those who write under his editorship hold heterodox views on the dangers of constipation, over-eating, cane-sugar, excessive sleep, and tight collars; rightly or wrongly we may not readily accept the advice to clean the nose with soap and water every time we deal with our face, or to wash the leather band inside our hats at least once weekly. But anyone who takes the trouble to examine the book at all carefully must recognise a fine sane purpose behind it—a purpose often finely executed and capable of working great good. There is much here that the intelligent layman (and his doctor) really ought to know but have never before been told so clearly.

SEPTIC ATMOSPHERES

THE existence of special wards for burns at the Glasgow Royal Infirmary has enabled Dr. ROBERT CRUICKSHANK to carry out a study the results of which are of far-reaching interest.⁵ The main fact which emerges is that within a short time of admission to the ward the majority of burns become infected with hæmolytic streptococci. Septic infection, as Dr. CRUICKSHANK observes, must be regarded as the source of the toxæmia

and fever which appear on the second or third day, and constitutes the principal danger after the initial stages; the idea that the absorption of protein-cleavage products accounts for unfavourable manifestations of this kind is no longer tenable. An observation of less apparent importance but of equal interest is that the proportion of patients with hæmolytic streptococci in their throats rises from 6 per cent. on admission to 25 per cent. during the first week in hospital. If this observation should be confirmed in a study of a larger number of cases it will repay careful consideration. The facts that hæmolytic streptococci could easily be cultivated from the air and dust of the ward, and that tonsillitis and scarlet fever occurred more frequently than in other wards, point in the same direction. There is surely some factor concerned in the spread of infection under these conditions which has not been recognised. A single throat carrier might well, according to our present knowledge, account for the infection of all the large vulnerable surfaces represented by a ward full of burns, or it might be suggested that the spread of this infection is due in part at least to indirect contact. But only increasingly heavy aerial infection can explain the condition of the air itself and the rise in the throat carrier-rate. Unless it is assumed that patients’ throats become infected from their own burns (and the mechanism by which this occurs, if it does, requires elucidation), this loading of the air with streptococci remains unexplained. It has yet to be demonstrated that aerial dispersion could possibly occur from a moist infected surface unconnected with the upper air-passages and innocent of any capacity to form droplets or other air-borne particles, and the mechanism of such dispersion is very difficult even to picture. If the transference of streptococci from person to person is achieved by some unsuspected route or favoured by some unknown factor, this would naturally have some bearing on the problem of puerperal sepsis. There is another field of medicine in which the activities of streptococci are without question remarkably favoured by hospital conditions. It is well known that clean operation sites are particularly liable to septic infection in ear, nose, and throat wards. Here there is no difficulty in explaining everything in terms of aerial spread, the vulnerable operation site becoming in its turn a source of further air-borne infection.

Nevertheless a study of the carrier-rate and of the bacteriology of the air itself in such wards might furnish illuminating data. Is there no method, short of segregation, which will obviate this very serious danger? The air in cinemas and even sometimes in trains is treated in an elaborate way for consumption by healthy people; air can be sterilised and adjusted to whatever conditions of moisture content and temperature may be considered desirable, and by a suitable system the direction of its currents can be controlled. Could not these devices, hitherto utilised chiefly to secure the comfort of theatre-goers and travellers, be applied to ensuring the safety of patients in hospital wards? Even if the physical condition of the air

⁴ *Ibid.*, 1926, II., 793.

⁵ *Jour. Path. and Bact.*, 1935, xli., 347.

were without influence on the survival of bacteria in it, a more rapid rate of exchange than window ventilation can secure, and such control of currents that air infected by one patient cannot simply drift across the beds of others, should greatly diminish risk from this source, and at least secure an atmosphere from which hæmolytic streptococci cannot be grown as readily and regularly as the colon bacillus from sewage.

MEDICINE AND THE WELSH LANGUAGE

At the recent annual meeting of the Association of Welsh Insurance Committees held at Barmouth, Mr. F. LLEWELLYN-JONES, M.P., expressed the view that the peculiar health problems of Wales were not receiving due attention. That these exist is beyond doubt chiefly because of the principality's predominantly rural character, its mountainous and sparsely populated areas, and its small counties of low rateable value, but also because of the high proportion of the people who can or prefer to speak only Welsh. Mr. LLEWELLYN-JONES attributed this alleged neglect to the fact that Wales was really governed in public health matters by the English Ministry of Health, although a Welsh Board of Health existed in name. When the Welsh Insurance Commission was constituted in 1911, they had been given to understand that its business would be to reform the whole of the health services of the principality and consultative committees had been set up to explore the whole field. Their reports, prepared after great deliberation, had been shelved. Welsh insurance committees were not consulted when new regulations were in preparation. Circulars issued from the Welsh Board of Health were mere replicas of those issued by the Ministry in England. Mr. JOHN ROWLAND, chairman of the Welsh Board, who followed him, drew attention to the improvement in health derived from the establishment of the modern health services, emphasising the decline of tuberculosis. Wales is unique in having a centrally administered tuberculosis scheme, all the counties and county boroughs having delegated their functions to the Welsh National Memorial Association. Mr. ROWLAND pointed out that, while the fall in the death-rate from tuberculosis had been less rapid in Wales than in England, it had been greatest in the western counties where it had formerly been exceptionally high. He made passing reference to the difficulty experienced by the Memorial Association in finding suitably qualified medical men and women who could speak the Welsh language and urged his listeners to take an interest in the Welsh National School of Medicine.

While some of Mr. LLEWELLYN-JONES's complaints might equally well be voiced in England and Scotland, there can be no question that knowledge of the Welsh language is an asset to those seeking appointments in Wales. Of a total population amounting to 2,593,332 persons in 1931, 97,932 spoke Welsh only and 811,329 spoke both English and Welsh, of whom, no doubt, many found it easier to express themselves in the

native language. The proportion of monoglot Welsh has fallen from 151 per 1000 in 1901 to 40 in 1931, but the decline in the number speaking both languages, which was noticeable but not so rapid up to 1921, has been arrested. Even among those of ages 15 to 24 years, among whom most of the medical students will be found, a proportion of 315 per 1000 speaking both languages would lead one to anticipate no difficulty in supplying the principality's need for Welsh-speaking officers. It has to be remembered, however, that certain other factors may invalidate this conclusion. The medical school is situated at Cardiff where Welsh is not customarily spoken (only 50 per 1000 in that city speak Welsh), and while Glamorgan has a comparatively large Welsh-speaking population, the proportion is low in the adjacent county of Monmouth and the town of Newport, from which students are also drawn. On the other hand, a large number of students from North Wales, where twice as many speak Welsh as in the South, graduate in Liverpool and other universities, so that a supply of candidates who have this special qualification might be expected from these sources, and in fact some do return to appointments in Wales. Probably the real trouble is that most of the Welsh students find practical difficulty in studying for the post-graduate qualifications required for official posts, and choose to enter private practice for financial reasons. It can readily be understood that local authorities and other statutory bodies, even though they consist almost entirely of Welshmen, find it impossible to make language the governing consideration in deciding appointments. However much they are inclined to favour Welsh-speaking candidates, the efficiency of their services must be their first concern.

ST. GEORGE'S HOSPITAL

A GIFT of an unusual kind has been made to St. George's Hospital, London, in aid of the rebuilding fund. The donor, who remains anonymous, has offered to pay for the preparation of preliminary plans for the new hospital. If these plans are accepted by the rebuilding committee his gift will be increased to cover the architect's fees for the whole work. It is estimated that the rebuilding fund, which now stands at £140,000, will thus benefit to the extent of a further £30,000 at least, and the committee has gratefully accepted the proposal. The new hospital is to be erected on the present site at Hyde Park Corner, and the appeal issued is for £1,000,000—a sum which should allow a margin for allocation to the endowment fund. We understand that the architects will be Messrs. Elcock and Sutcliffe of London.

It is hoped that the new gift will enable the committee to begin rebuilding at a much earlier date than was expected.

ROYAL MANCHESTER CHILDREN'S HOSPITAL.—This hospital, the largest of its kind in the North of England, will have to curtail its work unless there is an immediate response to its centenary appeal for £100,000. Since the appeal was made, four months ago, over £10,000 has been received. There are more than 100,000 attendances yearly at the out-patients' department.

ANNOTATIONS

MISFORTUNE PARTIALLY RELIEVED

THE Royal Medical Benevolent Fund has a good name—not only in the sense of reputation but literally. It is a spacious name, interpreting charity in its better sense. Its practical interpretation is still, however, based on a subscription income nothing like sufficient for the purpose. The annual report shows that last year this income was £11,092: returning economic prosperity and increased effort were reflected in an increase of £1676 over 1933 and in the support of 869 new subscribers. But even so the Fund is very far from adequate to meet the demands made upon it. Altruism apart, its activities are the personal concern of nearly every member of the medical profession; for which of us can feel completely confident of maintaining financial or even physical security for ourselves and our dependents in this kind of world? During 1934 the Fund gave financial help to 670 people to whom disaster was no longer a remote possibility but a dreadful fact. At present their needs can be met only to the extent of an annual grant of £40 to a practitioner and £26 to a dependent, and the support of the whole profession is needed if misfortunes in our ranks are to be relieved with a little more decent generosity. Next year will be the centenary year of the Fund, and the committee have considered carefully the idea of obtaining money by some public appeal, but have rejected it. Members of the profession will no doubt agree with this decision, feeling that we owe a service to our less fortunate colleagues which we cannot ask the public to share. The administrators of the Fund intend to invite all medical practitioners to become annual subscribers before the end of 1936, making this a fitting celebration of the centenary of a great charitable organisation. Meanwhile we may look for a wide response to Sir Thomas Barlow's Christmas appeal appearing in our correspondence columns this week.

PLASMA PROTEINS AND N.P.N. IN RHEUMATISM

In all clinical investigations it is important to choose controls of the same age and social circumstances as the group to be studied. The need for this precaution is well illustrated by a recent analysis of the plasma proteins, non-protein nitrogen (N.P.N.), and sedimentation rate in chronic rheumatic disorders by Dr. Aldred-Brown and Dr. Munro of Bath.¹ They have been able to demonstrate wide variations in the values obtained in (a) a group of healthy young adults, (b) subjects suffering from chronic rheumatic disorders, and (c) non-rheumatic persons whose age and economic stresses resembled the preceding group of chronic rheumatics. The range of values in Group (b) and Group (c) resembled one another fairly closely, but there were considerable differences between Group (a) and Group (b). The investigators suggest therefore that several factors, of which increasing age and economic stress may possibly be two, rather than the rheumatic processes, are at least in part responsible for these differences. Osteo-arthritis was found to show the least deviation from the normal. The mean average of the fibrinogen percentages in spondylitis ankylopoietica and rheumatoid arthritis was high, and also the mean average of the N.P.N. percentages in rheumatoid arthritis. The sedimentation rate was

also higher in patients with the latter condition than in other groups, though it is much increased in all types of arthritis. Aldred-Brown and Munro suggest that the lowness of their globulin and fibrinogen figures compared with those of other observers may possibly be due to the fact that their figures for total protein are lower than those usually recorded. Their figures for non-protein nitrogen are also lower. The significance of the variations in the sedimentation rate are to be discussed in a later paper, which will be in some sort a sequel to one published in our own columns last year.²

ASSOCIATION OF LOCAL GOVERNMENT MEDICAL OFFICERS

SIXTY-FIVE years ago the medical officers employed under the old Poor Law banded themselves into an association to ensure for their members proper remuneration and conditions of service. Six years ago, after the passage of the Local Government Act, the scope of the association was widened to include all medical officers working for municipal authorities, under the comprehensive title of The Local Government Medical Officers' Association of England and Wales. The Association supports the employment of part-time assistance medical officers, as opposed to a whole-time medical service, and is in favour of free choice of doctor in areas where vacancies occur and the local medical profession has approved this form of service. The Association is desirous of letting it be widely known that it will admit as an associate any registered medical practitioner who, without being a local government medical officer, accepts the principle of private practitioners carrying on public assistance medical service either by the part-time salaried method or by the free choice method where so adopted. Such associates pay a fee on joining of 2s. 6d., but not the annual subscription of 10s. At present the officers of the Association are: president, Dr. Alfred Cox; chairman of council, Dr. Percy Spurgin; hon. secretary, Dr. M. W. Renton, The Bridge House, Dartford, Kent.

MULTIPLE MYELOMA

WHEN the extent of involvement of the bone-marrow in multiple myeloma is considered it is a matter for surprise that anaemia is not a more pronounced and characteristic clinical feature of this disease. Possibly it calls for further attention in diagnosis. Thus U. Spiller and A. Revetas³ have recently emphasised the importance of multiple myeloma as a cause of "cryptogenic anaemia." They say that in 12 out of 432 cases of anaemia seen at the Martin Luther Krankenhaus in Berlin since 1931 the cause of the anaemia was obscure, and that 6 of these were later found to be examples of multiple myeloma. Leucopenia with relative lymphocytosis may precede both symptoms and the X ray changes of myeloma. Unfortunately in the 4 cases annotated by these authors the blood picture is not described in detail. In the interesting case published by C. F. Sweigert⁴ examination of the blood revealed a macrocytic anaemia: myelocytes, normoblasts, and on one occasion myeloblasts, he writes, were present. We have here evidently the leucoerythroblastic anaemia of Vaughan and Turnbull. Other interesting features

¹ The Blood Sedimentation Rate and the Plasma Proteins, THE LANCET, 1934, i, 1333.

² Deut. med. Woch., 1935, lxi, 1305.

³ Amer. Jour. Med. Sci., 1935, exc., 245.

⁴ Aldred-Brown, G. R. P., and Munro, J. M. H.: Quart. Jour. Med., 1935, iv., 269.

in this case were the existence of hyperproteinæmia, associated with excretion of Bence-Jones protein, and also clinical evidence of chronic nephritis combined with low blood pressure. The peculiar type of nephritis that is found in multiple myeloma has been neglected both by pathologists and clinicians until recent years. It is therefore of interest that Sweigert says of his case that "multiple myeloma was first suggested by the peculiar blood picture and evidences of an atypical nephritis. Although these are by no means constant or pathognomonic features of the disease their combination should always demand consideration of myeloma." The kidney picture has been further examined by American observers⁶ in a case which came to necropsy at the Johns Hopkins Hospital. The peculiar tubular casts and the foreign body reaction excited by their presence are stressed by these authors as characteristic of the condition, and the nature of the functional disturbance is regarded by them as obstructive in origin. Attempts to reproduce this specific nephritis in dogs, rabbits, and mice by repeated injections of Bence-Jones protein were unsuccessful, but it is possible that the negative results were due to the shortness of the periods over which the injections were carried out.

PROF. JUNG IN LONDON

THE Institute of Medical Psychology is rapidly becoming known as a centre of energetic research and instruction in psychology, both practical and theoretical. The visit of Prof. C. G. Jung to the Institute last week, where he delivered five seminars on "Fundamental Psychological Conceptions," was an important event in its short but increasingly distinguished annals. Prof. Jung's teaching is still too little known in this country. His books deal little with therapy; they are largely devoted to the explanation of the substantial body of knowledge he has helped to build up during the last 30 years on the racial and historical components of the human unconscious mind. This is his main interest but, at the same time, he is a busy practitioner, and those who imagine that he is chiefly concerned with mystical philosophy are profoundly mistaken. Some may have had this view effectively shattered by their experience of him last week. The audience had been limited to about a hundred of the leading psychotherapists of the country, with a sprinkling of medical graduates and university workers. It was, therefore, composed of people well acquainted with his books, and when he spent the first two lectures on a discussion of psychological types and the association test—and even expressed reluctance to answer questions that went deeper—many of them naturally felt that he did not appreciate either the intense interest which English psychotherapists take in his work or the overwhelming difficulties which they have encountered in making contact with him and learning the exact meaning and practical applications of his work. When this unrest had expressed itself in the medical discussion which followed the second seminar, Prof. Jung set himself to meet the need, and the last three lectures were a wealth of good things.

Much as his hearers benefited from listening to Prof. Jung's brilliant account of his explorations into the vast country of the human mind, they must have benefited equally from the intimate contact of five consecutive, intensely active evenings with his personality. They listened to this robust, burly man, with his white hair and moustache, ruddy face,

and general appearance of exuberant health and good spirits, as he lectured in his own inimitable way—sometimes easy-going, sometimes jovial, with bursts of infectious laughter, often vigorous and trenchant, occasionally stern and uncompromising. Prof. Jung not only has material to impart but has the rare gift of knowing very well how to impart it. His privileged audience had a treat which they will not soon forget, and they will look forward eagerly to his next visit.

THE POTATO

A BROCHURE¹ issued by the Potato Marketing Board makes extensive claims for the potato as an article of food, and not one of these claims is without foundation. Compared with the cereals, potatoes owing to their high water content are a less cheap form of energy producer, but they have so many other advantages that it is unfair to make the comparison purely on the basis of energy production. The quality of potato protein is at least equal, if not superior, to that of the cereals, and in vitamin content and salt balance it surpasses them. Potatoes supply vitamin C and the vitamin-B complex, and though their supply of vitamin A as carotene is small, judicious selection and propagation of yellower varieties might be able materially to increase it. Neither pellagra nor beri-beri is recorded in persons subsisting mainly on potatoes, showing that the vitamin-B complex is well supplied. The good vitamin-C content of the potato is perhaps one of its greatest assets. The tubers are capable of storage for many months, throughout which the vitamin-C content is well maintained; for persons on poor and monotonous diets over long winters, the potato must be one of the greatest protective factors. The occurrence of scurvy in Great Britain in the spring of 1917, when the potato supply fell short, witnessed to this. Potatoes yield an alkaline ash and are therefore preferable to cereals in diets where a preponderance of base-forming principles is desired. Some at least of the cereals appear to be actually rachitogenic and antagonistic to normal healthy tooth formation; the potato, it seems, has no such property. Whether this property is due to a toxin or to the presence of a large proportion of the phosphorus in cereals in a non-available form, and even in a form which militates against the absorption of calcium also, is still not quite certain.² The well-known and astonishingly favourable results of the survey of the teeth, made recently among the islanders of Tristan da Cunha, were a striking testimonial for the potato; for it, far more than any cereal, is the staple energy producing food of the island. There seems little doubt that a considerable proportion of the cereal in the diet of most people in Great Britain could be advantageously replaced by potato.

Even if replacement of cereal in the diet by potato may not be easy to achieve, a second publication of the Potato Marketing Board³ shows that simple addition of more potato to the diet is made possible merely by reducing the price. The Board carried out an experiment to ascertain whether lowering of price of a staple foodstuff would increase consumption. Most housewives with a slender house-keeping allowance could presumably have given an answer without needing any experiment to settle the question. It was however desired to obtain an

¹ The Potato as an Article of Diet. By H. K. Archbold. D.Sc. Lond., D.I.C., A.I.C. London: Potato Marketing Board, Africa House, Kingsway, W.C.2. Pp. 20. 6d.

⁶ Forbus, W. D., Perlzweig, W. A., Parfentjev, I. A., and Barwell, J. C.: *Bull. Johns Hopkins Hosp.*, 1935, lvi., 47.

answer even in the most unlikely conditions, where the price of the foodstuff was already comparatively cheap so that the total reduction in expenditure would only be small. It was also desired to make the experiment where purchasing power was very small. A mining village in the county of Durham was therefore selected as being one where the percentage of those unemployed for continuous long periods was very high. There were 2437 unemployed (insured) male workers, with 3799 dependants, in a population of 5000 insured workers and 19,000 total inhabitants. The experiment was confined to the families of the unemployed and was carried out in February and March. Families containing up to three persons could purchase $1\frac{1}{2}$ stone of potatoes weekly, and larger families proportionately more. Instead of paying $10\frac{1}{2}d.$, the ruling price for this amount, the $1\frac{1}{2}$ stone could be bought for $6d.$, thus saving $4\frac{1}{2}d.$ a week. It was also particularly desired to test how the trade of retailers of potatoes in the area would be affected and the coöperation of the shopkeepers was secured. The full number of vouchers for cheap potatoes was issued and only 7.3 per cent. of these were not used. The normal sales of potatoes in the retail shops fell by 40 per cent., but the total consumption in the whole area rose by 96 per cent. When this figure is corrected for any possible source of error, an increased consumption of 69 per cent. is still shown. The main thesis—that increased consumption will result from lowering the price of an already cheap staple foodstuff, when purchasing power is very small—appears therefore to be proved, as it was scarcely possible to doubt that it would be. But to implement this conclusion is another matter.

MEDICAL STUDENTS ABROAD

ACCORDING to a report¹ by the Council on Medical Education and Hospital it appears that 710 Americans enrolled as medical students in schools outside the United States in the academic year 1930-31. If still studying abroad these students will probably finish their course during this year or next, and it may be expected that most of them plan to return to the United States to practise. It was a consideration of the problem created by this migration that led the Federation of State Medical Boards to harden their hearts against American students matriculating abroad and not to admit them to any licensing examination without producing satisfactory evidence of pre-medical education. The numbers in question are still by no means negligible, for during the last academic year 1934-35 there were known to be 1471 American students training in 97 institutions abroad, and 199 who graduated or completed their medical training during that time. The report contains a caustic remark that of 502 students whose names were supplied to the Association of American Medical Colleges this year 106 had made application to medical schools in the United States without success since 1931, and it is hinted that some of these students have signified their inability to obtain a medical education in the U.S.A. by rejection at 25 different medical schools. Various European countries have, it seems, sent representatives to the U.S.A. to discuss measures for dealing with the students who come over, and it may be interesting to note which European schools at the present time especially are offering hospitality to American students. For the academic year 1934-35 the highest numbers of students were enrolled, in descending

order, at Edinburgh Royal Colleges 190, University of Rome 161, University of Bern 114, University of Basle 83, University of Zurich 72, University of St. Andrews 69, University of Paris 63, Friedrich-Wilhelm University, Berlin, 62. A footnote to the table of figures suggests that the totals of 1471 enrolled and 199 who completed course should be larger, inasmuch as the following schools, viz., Vienna, Bologna, Naples, St. Mungo's, Glasgow, and Geneva, which previously reported large numbers of American students, do not now figure in the list.

SKIN DISINFECTION

USERS of Harrington's solution may be interested to know that its virtues have been rediscovered in the United States. J. A. Vaichulis and Lloyd Arnold, who make no reference to Harrington's solution, have presumably repeated the steps in argument or experiment which led to its formulation, for the skin disinfectant evolved by them¹ contains almost identical amounts of mercuric chloride, hydrochloric acid, and alcohol; it differs in containing also 10 per cent. of acetone and 0.2 per cent. of chrysoidin Y, the former serving to dissolve fat and thus assist penetration, the latter giving characteristic colour and some added disinfectant power. The phenol coefficient of this solution, using *Staphylococcus aureus* as the test organism, was found to be 357. It is cheaper than tincture of iodine and much cheaper than solutions of other mercurial compounds such as mercurochrome or metaphen, and it is said to have been used successfully not only for preparing the skin in 185 cases of operation on the neck or abdomen, but in 300 cases of gunshot wounds and automobile accidents, another matter altogether, since the sterilisation of intact skin and the disinfection of a wound are quite different problems. These claims involve two questions which are in a highly unsatisfactory position. One is the true disinfecting capacity of mercury salts under clinical conditions. Although Geppert exposed the fallacy in Koch's original experiments with mercuric chloride no less than forty-five years ago, numberless papers have continued to appear up to the present day reporting experiments in which inhibitory as distinct from bactericidal action is ignored. The conditions of a test of mercuric chloride can be so arranged as to give almost any result, but the nearer those conditions approach to those obtaining in the body, which is tantamount to saying the richer the medium employed, the less does its disinfecting power appear to be. It is very desirable that a test suitable to the peculiar action of the heavy metals should come into general use. The second question does not arise directly from this paper, since no observations of the kind were made by Vaichulis and Arnold; it concerns the proper method of determining whether or no skin has been disinfected. Various authors have scraped or swabbed treated areas; Tinker and Sutton² excised strips of skin from the edges of operation wounds, and others have cut portions of skin from animals, to furnish material for cultivation. Colebrook's method³ differs from all of these in securing adequate dilution of the inoculum and in furnishing quantitative results. This is admittedly a proceeding not lending itself to exact definition, but a nearer approach to uniformity of method would make it possible (which at present it is not) to compare the results obtained by different experimenters.

HAROLD WARD DUDLEY, F.R.S.

THE death on Oct. 3rd of Mr. H. W. Dudley, Ph.D., F.R.S., at the early age of 47, removes one of the outstanding research workers in biochemistry as applied to medical problems. As a student at Leeds he came under the influence of J. B. Cohen, one of the first organic chemists in this country to see the promising future that lay before biochemistry. A research scholarship enabled him to spend two years in Berlin working at the structure of purines under Wilhelm Traube in Emil Fischer's laboratory; from there he went to Herter's laboratory in New York where he met H. D. Dakin, another of Cohen's old students, and entered into a fruitful collaboration with him. Most noteworthy perhaps was the discovery of the enzyme glyoxalase, which rapidly converts methyl glyoxal at body temperature to lactic acid. During the late war he was attached to the R.A.M. College in London, and was sent to the United States in charge of an anti-gas mission. On his return to England he joined the staff of the Medical Research Council as chief biochemist, a post that brought him into close contact with colleagues working in many different fields of medical research, to whom he gave freely of his deep knowledge of chemistry and his skill in complex analysis.

The first problem presented to him was that of the chemical nature of the constituents of the posterior lobe of the pituitary body; he was able to show that the pressor constituent and the constituent responsible for causing contraction of uterine muscle were separable by chemical means. He then turned his attention to the newly discovered insulin, and was the first to devise a method of preparation (still used in its manufacture) which gave a dry stable product having ten times the activity of the original crude material, and to suggest that the hormone itself was a complex protein derivative—a conclusion amply confirmed later by other workers. Meanwhile in collaboration with O. Rosenheim and W. W. Starling he proved the constitution of spermine and spermidine, two bases now known to be general tissue constituents for which no physiological function can yet be even suggested. The importance of certain vasodilator constituents of the animal body with a histamine-like action for the normal functioning of the capillaries had long been emphasised by Sir Henry Dale. Dudley, in collaboration with W. V. Thorpe, was able to identify the substance having this action with histamine itself, which was isolated from several organs under conditions which precluded putrefactive changes. Next came a brilliant research with Dale which led to the isolation of acetylcholine from horse and ox spleen. Here Dudley's analytical skill was shown at its best; his method of separating this unstable substance from choline and other substances present by means of their chloroplatinates bears the stamp of genius.

Dudley's last research, which was fortunately brought to a successful conclusion before his untimely death, dealt with the active principle of ergot. It had been assumed that the substances active towards the uterine muscle were the alkaloids ergotamine and ergotamine, but in 1932 Chassard Moir obtained direct evidence that aqueous extracts of ergot free from these complex alkaloids were active when administered by the mouth. The active principle must therefore be different from any of those known hitherto and Dudley undertook a chemical investigation of this unknown substance in association with the direct clinical observations of Moir. The result was the isolation of a new water-soluble alkaloid,

ergometrine, which in minute doses has the characteristic activity of ergot. This discovery of ergometrine, which solves a long-standing problem of the pharmacology of ergot and its use in therapeutics, has aroused widespread interest, as is shown by the fact that it has already been confirmed, in effect, in three other laboratories where research was independently in progress. While his main interests were definitely in the laboratory Dudley did not neglect those other biochemical activities which he was called upon to perform. From 1922-24 he was secretary of the Biochemical Society, and from 1925-30 joint editor with Prof. Harden of the *Biochemical Journal*. He was also for many years an assistant editor of *Chemical Abstracts* and was responsible for the high level of the section of abstracts dealing with biochemistry. His great attainments were recognised in his election to the fellowship of the Royal Society in 1930.

EARLY DIAGNOSIS OF AORTIC SYPHILIS

SYPHILIS of the aorta usually causes death within a few years of its clinical recognition. Affecting most often the ascending portion of the vessel it is liable to damage the mouths of the coronary arteries and the cusps of the aortic valves. If the inflammatory process is confined to the transverse or descending part of the arch, these vital structures escape and the prognosis is much less grave.

There is reason to think that the aortic wall is invaded early in the course of syphilitic infection, and that it is not until the destructive process has been at work for many years that symptoms arise and the diagnosis of aortic syphilis is made. Hence the relatively poor results of treatment. In many diseases subjective symptoms, indicating altered function, precede any detectable alteration in structure. In aortic syphilis, however, it has been suggested that a structural change may be recognised long before symptoms arise. E. P. Maynard and co-workers¹ claim to diagnose such cases radiographically, and they have been able to investigate 346 patients by working in coöperation with a syphilis clinic, and investigating the cardiovascular system of every patient attending it, irrespective of the stage of the disease and the symptoms complained of. All who have studied the X ray appearances of the aorta will appreciate, nevertheless, that the recognition of slight abnormality in the width of this vessel is not easy. The width varies with age and with the shape of the chest, and can be altered by other factors such as atheroma and high blood pressure. The investigators use the method of Vaquez and Bordet for measuring the vessel width, and after excluding cases with high diaphragm, scoliosis, a systolic pressure over 140 mm. Hg, or rheumatic aortic lesions, and patients with arteriosclerosis or over fifty years of age, they accept any measurement over 7 cm. as pathological, and one between 6 and 7 cm. also, if the ascending aorta is prominent. Of 77 patients examined within nine years of infection, 14 had aortic syphilis, but only 4 of these had symptoms referable to the lesion. The proportion with aortitis gradually increased with the period since infection, and so did the proportion of these with symptoms; out of 17 patients examined thirty years or more after infection 15 were found to have cardiovascular syphilis. In the 145 patients who showed evidence of aortic syphilis the mean interval between infection and evidence of

¹ Arch. Internal Med., 1935, lv., 873.

cardiovascular syphilis was twenty years; yet in 25 per cent. it was within ten years.

On the other hand, H. Schlesinger² thinks that certain clinical features are sufficient for an early diagnosis, even in the absence of X ray changes and of a positive Wassermann test. He attaches importance to certain signs usually considered too late in appearance to be of value, such as a distant first, and a ringing second aortic sound in conjunction with a low systolic pressure, aortic incompetence, and a systolic murmur at the aortic area. Symptoms which he regards as of great diagnostic value include dyspnoea of sudden onset and without obvious cause, and aortalgia—i.e., retrosternal pain not related to effort. Severe and long-lasting retrosternal pain, similar to that of atheromatous coronary occlusion, is also described, but it is stated that there is no sense of impending death, and that this is an important point in differential diagnosis. This symptom, however, is thought to-day to be neither constantly nor specifically related to coronary occlusion, and its absence cannot therefore be held to be of much help in diagnosis. Many of these symptoms obviously depend on lesions involving the aortic cusps and coronary orifices; and it would seem that when these complications have developed the pathological process has gone too far for diagnosis to be of much value.

CHEMOTHERAPY IN STREPTOCOCCAL INFECTIONS

THE limitations of chemotherapeutics in controlling infective diseases are as remarkable as its successes. In a lecture delivered to the section of tropical diseases and parasitology of the Royal Society of Medicine on Oct. 3rd Prof. H. Hörlein, of Düsseldorf, elaborated the thesis that the possibility of combating infective diseases with chemotherapeutically active substances depends to a large extent on the structure of the pathogenic organism. The more highly developed the pathogenic organism, the more points for attack it appears to offer to the action of chemotherapeutic substances. Many infections with different kinds of protozoa and spirochaetes have yielded to appropriate synthetic remedies, but bacterial infections generally have hitherto proved disappointingly resistant to such agents; and apart from the cure of contagious pleuro-pneumonia in horses with neoarsphenamine, we have, as yet, no chemotherapeutic substance which is active in virus diseases. Not only spirochaetal diseases such as syphilis, relapsing fever, frambosia, and protozoal diseases such as trypanosomiasis, malaria, amoebic dysentery, and leishmaniasis, but epizootics resembling human diseases are also relatively easy to deal with by synthetic drugs. Diseases of animals which, though attributable to protozoa, are not closely related to the tropical diseases of man are not amenable to such treatment. The most important of these epizootics are the piroplasmoses, which are caused by babesiae and theileriae and are found not only in tropical and subtropical regions but also in temperate zones. Piroplasmosis is a condition marked by chronic irregular fever, enlargement of the spleen, bronchitis, oedema of the feet, subcutaneous haemorrhage, and diarrhoea. It affects dogs, horses, sheep, and oxen. Trypan-blue, originally recommended by G. H. F. Nuttall for this condition has been used against the disease with some measure of success. Prof. Hörlein claims that a new compound Acaprin prepared in his laboratories is three times as

active as is trypan-blue for piroplasmosis. Even more interesting, however, are his claims for two other new compounds Prontosil and Prontosil S., which are said to be potent against infections caused by haemolytic streptococci. The results of the

administration of either of these two compounds, which can be given by mouth or by subcutaneous injection, to mice experimentally infected with this organism by the intraperitoneal route have been so encouraging as to lead to their trial in human patients. 1500 case records are now available in Germany of acute infections caused by the *Streptococcus haemolyticus* and treated by prontosil or prontosil S. These infections included many cases of puerperal sepsis. The results as a whole were described by Prof. Hörlein as being strikingly successful, though exact figures are still to come. In the course of the discussion Dr. G. A. H. Buttle, working at the Wellcome Research Laboratories, described his own experience with the drug in infected mice. Whereas in Prof. Hörlein's series all the afflicted mice recovered, Dr. Buttle, using different strains of streptococci, was not successful in doing more than delaying death. But it emerged that certain differences in technique might have accounted for the discrepancy, and Dr. Buttle left no doubt in the minds of the audience that the new compound is therapeutically active; the point at issue is only one of degree. Dr. P. Manson-Bahr, who presided over the meeting and translated Prof. Hörlein's replies, which were made in German, with considerable skill, voiced the impression of all present that a contribution to chemotherapeutics had been made by Prof. Hörlein and his co-workers which might indeed prove to be monumental.

NEXT Friday, Oct. 18th, Sir Henry Dale, F.R.S., will deliver the Harveian oration of the Royal College of Physicians of London. His title is Some Epochs in Medical Research.

THE Metropolitan Hospital last week announced its incorporation as a company limited by guarantee. The management committee will thereby avoid personal responsibility for the discharge of the hospital's liabilities, should the assets at any time be insufficient for the purpose. Such a responsibility, however remote, might, it was felt, deter persons whose services would be valuable to the hospital from joining the committee. When the Queen's Hospital for Children recently took a similar step we pointed out the convenience to a hospital of becoming an independent legal entity with an existence separate from the existence of the total of its members. The system of incorporated companies dispenses with the system of trustees.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LXXII.—PROGNOSIS IN CEREBRO-SPINAL FEVER

WITH a disease so variable in its course as cerebro-spinal fever, prognosis is often difficult to determine. Cases admitted to hospital in an apparently hopeless condition of coma may recover, while others, from all appearances mild in character, prove fatal owing to the subsequent development of internal hydrocephalus or of a progressive increase in the purulency of the cerebro-spinal fluid.

The various factors on which an opinion may be based are as follows :—

GENERAL CONSIDERATIONS

Early diagnosis.—This factor is of paramount importance as the earlier the disease is diagnosed the earlier can serum treatment be instituted. All observers agree that early treatment by means of lumbar puncture and serum administration is one of the most hopeful of prognostic indications. One should always perform lumbar puncture in doubtful cases rather than lose the opportunity for the early application of treatment.

Stage of epidemic.—During the early stage of an epidemic fulminating cases are more frequent than in the later stages, when the disease is usually milder and less liable to prove fatal.

Age of patient.—The mortality is distinctly heavier among infants and adults over forty. Infants under two years of age show the greatest mortality (80 per cent.); after two years the death-rate tends to decrease towards the fifteenth year. It then rises again showing a slight fall between 20 and 30. After 30 it rises considerably and increases with each subsequent decade.

Previous health.—The presence of chronic nephritis, chronic alcoholism, or latent tuberculosis impairs the patient's chance of recovery. Apart from such conditions, general health and constitution have little apparent influence; strong and robust individuals often die rapidly while those of poor physique recover.

Mode of onset.—A gradual onset is usually more favourable than one that is sudden and abrupt. The absence of vomiting at the onset of other than fulminating cases is of somewhat favourable import. Early loss of consciousness does not necessarily indicate that the outlook is bad.

Type of case.—The term "fulminating" or "malignant" is applied to those cases beginning abruptly and proving fatal within 24 to 48 hours of the onset. They are frequently met with early in an epidemic. It is in this type of the disease that the purpuric eruption, consisting of large plum-coloured spots, is most often seen, and has produced in the lay mind the dread associated with the name "spotted fever."

The prognosis in the posterior basic type of infants is also bad, the mortality being about 70 per cent. The type termed by A. M. Kennedy and myself "progressively purulent type," in which there is a gradual and progressive increase in the purulent consistency of the fluid obtained by lumbar puncture, is invariably fatal. In subacute cases the outlook is more hopeful than in acute ones (14 per cent. as compared with 55 per cent. in acute cases of all types).

Temperature and pulse.—The temperature and pulse-rate during the first day or two are guides merely to the severity of the disease and have no definite

prognostic value. Continued hyperpyrexia during the course is of exceedingly grave import.

Cerebro-spinal fluid at the first lumbar puncture.—A purulent (yellowish) fluid obtained at the first lumbar puncture is of graver significance than a merely turbid (whitish) one, but by no means indicates that the patient will not recover. Excluding fulminating cases, among those showing merely a turbid fluid at the first lumbar puncture, recovery resulted in 77 per cent. of our own cases. From the presence of numerous meningococci on microscopical examination of the first samples of cerebro-spinal fluid obtained, no definite conclusions as regards prognosis can be drawn, but failure to find the diplococci after prolonged search is distinctly favourable.

Type of coccus.—In general, the isolation of a type II. (Gordon) coccus appears to offer the most favourable prognosis. During the war, the mortality of our type II. cases was 30 per cent. as compared with 40 per cent. for type III. Type I. coccus is somewhat resistant to treatment and usually gives rise to severe forms of the disease (60 per cent. mortality).

Method of treatment.—Most observers agree that the intrathecal administration of serum remains the method of choice and that the lumbar route is preferable to the cisternal. Cistern puncture entails more risk—especially of hæmorrhage—even in skilled hands, and there is no evidence that serum is any more efficacious when given by this route. Also, the subarachnoid space cannot be so adequately drained as by lumbar puncture. The administration of serum in the lumbar region entails practically no risk, and it has been shown (Carnegie Dickson: Brit. Med. Jour., 1917, i., 454) that solutions injected into the subarachnoid space by lumbar puncture penetrate readily into the chain of cerebral ventricles, reaching even to the tips of the lateral ventricles. Some authorities prefer to give serum intravenously, either with or without intrathecal injection, especially during the first few days of illness and in cases showing a petechial rash.

Serum administration may cease when organisms have disappeared from the cerebro-spinal fluid and the patient is improving, but drainage of the subarachnoid space by lumbar puncture should be continued daily until the cerebro-spinal fluid is practically clear.

SPECIAL FEATURES

Rash.—If well-marked purpuric blotches (vibices) are present the case is nearly always fatal. A petechial rash appearing on the first or second day is sometimes said to be unfavourable. In my experience, however, fully 50 per cent. of these cases recover.

Mental changes.—Intense restlessness occurring early in the disease is of rather more serious import than delirium. Nevertheless, if delirium increases the prospect of a favourable termination becomes worse. Hallucinations occurring after the third or fourth day are unfavourable; they are often present in the progressively purulent type of case which invariably proves fatal. Cases in which mental symptoms are entirely absent nearly always recover.

Head retraction.—This symptom occurring in adolescents and adults is by no means so unfavourable a sign as has been supposed by some writers. In a series of military cases, 18 years of age and over,

who showed marked occipital retraction during the course, 60 per cent. recovered.

Motor disturbances.—Catching at imaginary objects and picking at the bedclothes (carphology and floccitation) are unfavourable signs. Also a convulsive seizure occurring in an adult must be regarded seriously; in infants convulsions have not the same significance. Nystagmus is sometimes associated with internal hydrocephalus, the prognosis of which is grave.

Condition of sphincters.—From the presence of retention or incontinence during the early stages of illness, no conclusion as regards prognosis can be drawn. These symptoms, however, occurring later in the course constitute an unfavourable development. When incontinence is suddenly replaced by retention the outlook is grave rather than otherwise.

Abdominal reflexes.—These reflexes are often diminished or absent early in the disease. Their return or increase is a sign that the patient is progressing favourably. Similarly, their disappearance is an unfavourable indication. Cases in which they are retained throughout usually recover.

Herpes.—The presence of facial herpes has been thought to furnish a sign indicating that the patient's chance of recovery is distinctly favourable. It is true that most cases showing herpes recover, but its occurrence is of no definite value. In our own series of cases in which facial herpes developed the mortality was 23 per cent.

Blood pressure.—The presence of a continued low blood pressure, especially below 100 mm. Hg, during the first two days of illness is of grave significance.

Arthropathies are considered by some authors to be of good prognosis as regards ultimate recovery from meningitis; in our experience the mortality in cases with this complication is nearly 50 per cent.

The development of *pneumonia* as a complication is a most serious but not necessarily a fatal occurrence.

Pericarditis nearly always heralds a fatal termination.

CEREBRO-SPINAL FLUID DURING THE DISEASE

Quantity.—The daily evacuation of 40 to 70 c.cm. of cerebro-spinal fluid is more hopeful than when only small amounts are obtained; the latter may indicate impending internal hydrocephalus or increasing purulency. A "dry tap," provided one is quite certain that the subarachnoid space has been entered, is a most unfavourable sign. At least three different interspaces should be entered before a "dry tap" is regarded as conclusive. Cisternal puncture is then advisable.

Density.—Rapid or gradual decrease in the turbidity of the fluid is the rule as recovery proceeds and is an indication that the case is progressing favourably, providing fair quantities of fluid are obtained. Increase in the thickness and purulency of the fluid leading to difficulty of withdrawal through the lumbar puncture needle is one of the gravest of signs. It is seen in cases of the progressively purulent type and invariably leads to a fatal result.

Glucose reaction.—Persistent absence of glucose in the cerebro-spinal fluid is of distinctly bad prognosis. The return of glucose, having previously been absent, heralds definite clinical improvement; a recrudescence, however, may occur during which it again disappears. The glucose reaction invariably returns as the patient recovers.

Bacteriological findings.—On the whole, failure to obtain meningococci in culture from fluids subsequent to that withdrawn at the first lumbar puncture is a good prognostic sign. On direct microscopical examination of films of the cerebro-spinal fluid, the

presence of intracellular organisms is generally a more favourable sign than when they are chiefly extracellular. If extracellular forms predominate the case is not doing well.

COMPLICATIONS

Internal hydrocephalus.—The occurrence of hydrocephalic symptoms must be viewed with extreme gravity. Repeated lumbar puncture, however, may alleviate the generalised form. Even when internal hydrocephalus (closed meningococcal infection) is present the prognosis is not necessarily hopeless if appropriate measures of treatment are adopted.

Hemiplegia is not common, but may appear both in acute and subacute cases and often late in the disease. In some cases it is transitory, lasting only about 36 hours; in others it may be more permanent. In general the prognosis of hemiplegia occurring during the course is good, but when the paresis lasts for some time a residual palsy often remains. In rare instances an intercurrent cerebral hæmorrhage may occur, especially in patients with pre-existing nephritis or hyperpiesis; if not fatal it usually leads to some degree of permanent hemiplegia.

Monoplegia.—A flaccid paralysis localised to one limb or even a group of muscles is occasionally met with. Sometimes the condition is merely transitory and passes off within a day or two. In other cases however, the paralysis is more persistent and leads to the disappearance of the deep reflexes and muscular atrophy. These pareses appear to be due to involvement of anterior spinal nerve-roots, probably as a result of purulent infiltration of their pia-arachnoid sheaths. Unless the paralysis is extensive the prognosis is hopeful as regards ultimate recovery of movement.

Paraplegia is almost invariably of the flaccid variety, resembling that seen in acute myelitis. The prognosis is bad and the case usually proves fatal. Weakness of the legs and unsteadiness of gait with exaggerated deep reflexes is frequent during the early stage of convalescence. As a rule improvement is rapid.

Peripheral neuritis is rare, but may occur quite apart from the flaccid paralyses already mentioned. Recovery is the rule, although loss of the deep tendon reflexes may persist.

Keratitis.—In severe cases superficial corneal ulcers may develop in the absence of other ocular complications; they usually heal without perforation.

Irido-choroiditis.—This grave complication is fortunately rare. Loss of vision is the usual sequel, the eyeball becoming atrophied and the lens opaque. Occasionally an irido-choroiditis may lead to panophthalmitis; if this occurs and the patient recovers from the meningitis the affected eye usually remains permanently blind.

Orbital cellulitis is extremely rare. When it occurs it often terminates in thrombosis of the cavernous sinus with a fatal result.

Amaurosis.—This is a comparatively rare complication, and is most frequent in the posterior basic type of the disease affecting infants (about 30 per cent.). Occasionally blindness may appear somewhat suddenly and pass off after a certain period. In the other cases the blindness is permanent.

Deafness of central origin.—Deafness occurring at the outset or very early in the course of the disease may show a gradual disappearance as the patient's general condition improves. In most cases of temporary deafness improvement in hearing is noted only during convalescence. If recovery does not

occur then the patient is likely to be permanently deaf. In these cases it is always bilateral and usually appears early in the disease, rarely later than the first week of illness.

Pyelitis.—This complication is frequent in some epidemics while in others it is rare or absent. The pyelitis is of a benign type and never develops into true surgical kidney.

Nephritis is an infrequent complication. The possibility of pre-existing nephritis has to be borne in mind. In these cases the prognosis as regards life is unfavourable. In nephritis occurring as a direct complication of the cerebro-spinal fever the prognosis is good.

Epididymitis is occasionally observed during the early days of convalescence when a patient has

recovered from the actual meningitis. The inflammation subsides in from ten to twenty days.

Arthropathies.—The joint lesion appears to be a synovitis rather than a true arthritis. Unlike gonorrhoeal arthritis, involvement of the peri-articular tissues leading to adhesions and ankylosis is exceedingly rare. Not infrequently the joint condition is merely transitory, the effusion disappearing within a few days and leaving the joint apparently normal. At other times the arthropathy is more persistent, but eventually disappears if the patient recovers from the meningitis.

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

SECTION OF PATHOLOGY AND BACTERIOLOGY

At a meeting of this section, presided over by Prof. A. MURRAY DRENNAN (Edinburgh), a discussion on

The Problem of Calcification

was opened by Dr. F. HANSMAN (Sydney). After describing briefly the process of calcification and ossification in the normal development of bone, he spoke of the chemistry of osteoid tissue and the state in which the calcium salts are laid down in this tissue. It appeared, he said, that calcium carbonate and phosphate are deposited together in crystalline form, but apparently not always in the same proportions. In blood plasma calcium probably existed principally in the form of calcium proteinate, which ionised as a weak electrolyte into calcium ions and protein ions. The precipitation of calcium from serum or lymph to form bone salts in the matrix of cartilage and osteoid was controlled by what might be termed an "enzyme complex," consisting of the enzyme phosphatase, some second calcifying factor as yet ill-defined, and vitamin D. It was necessary to postulate the existence, in hypertrophic cartilage and osteoid, of this second calcifying factor, because phosphatase was known to be present in many other situations in which however calcification did not occur. Recent work suggested that it was the second calcifying factor which was influenced by vitamin D. Dr. Hansman then went on to discuss the interdependence of ingested calcium, phosphorus, and vitamin D for calcification. Dietetic experiments with various animals showed that improper Ca : P ratio, as well as vitamin-D deficiency, may occasion a variety of bone diseases which have their counterparts in human pathology, though the exciting causes may not always be the same in man and animals. In discussing the amounts of calcium and phosphorus required for normal calcification in growing children, Dr. Hansman cited Sherman's estimate that at least one gramme of calcium a day is necessary, an estimate which, however, he regarded as too high. From his own survey of the diets of 200 normal children of the working and middle classes in Sydney, it appeared that 0.5 g. or less of calcium per diem was adequate. The requirements of phosphorus in the diet could not be similarly considered,

because much of the phosphorus was needed for metabolic processes other than calcification; but there was evidence that the problem of phosphorus requirements was more important than that of calcium requirements.

Prof. P. MACCALLUM (Melbourne) said that calcification occurred in two main situations: (1) in the hyaline matrix of cartilage or bone, and (2) in areas of necrotic tissue. Before we could understand completely the process of deposition of bone salts, we would need to know more of the properties of the mucoproteins present in cartilage and ossein. Hydrogen-ion concentration must be important. With regard to the state of vitality of the hypertrophic cartilage cells before calcification, the presence of a healthy looking Golgi apparatus in these cells suggested that they were not senescent but were healthy viable cells. Calcification in dead tissue was of much interest. How did the calcium reach the dead material? There was probably a definite topographical relationship to the circulation—witness the frequent presence of multiple discrete foci of calcification in the dead material, and also the frequently peripheral distribution of calcification in such lesions.

Dr. E. S. J. KING (Melbourne) referred to the experiments of Huggins which he had repeated. If bladder epithelium was transplanted into the abdominal wall of dogs, calcification and ossification took place in the tissues external to the regenerating part of the epithelial cyst which developed, and the fluid contents of the cyst contained phosphatase.

Dr. R. A. WILLIS (Melbourne) said that the experiments of Huggins had in part been anticipated by several German workers of last century, who had found that, after ligation of the renal pedicle in rabbits and other animals, plates of bone developed around the pelvis of the damaged kidney. Dr. Willis had repeated this experiment in rats and had obtained a like result.

Dr. R. D. WRIGHT (Melbourne) said that examination of sections of non-decalcified bones made it evident that the bone salts were deposited in very finely crystalline form. In a sequestrum the particles of calcium salts were much coarser, and there was also conspicuous loss of protein. The crystals of bone salts also exhibited a characteristic orientation, and it might well be that the increased skiagraphic density of sequestra was due, not to raised calcium content, but to loss of the proper orientation of crystals so that greater reflecting surfaces were presented to X rays.

Dr. J. V. DUNG (Brisbane) had been specially

interested in calcified arteries, in which the Ca : P ratio and also the phosphate : carbonate ratio were almost constant and corresponded closely with the ratios in normal bone. His observations on the calcification of costal cartilages, which was very capricious, suggested to him that it depended essentially on the presence of vascular lesions, and he thought that calcification in general might well be studied from this point of view.

Dr. HANSMAN, in reply, said that like Prof. MacCallum he believed that the hypertrophic cells of calcifying cartilage were not moribund but healthy and functional. With respect to Dr. Duhig's remarks on arterial degeneration, there were many other factors—e.g., the metabolism of lipid—which made this problem a complex one difficult of analysis.

Pathology of Osseous Tissue

The PRESIDENT (Prof. Drennan), in opening the second discussion, said that bone differed from soft tissues only in that it was a hard tissue with a high mineral content. Its hardness was the main factor in modifying pathological changes in the tissue—for example, the slow removal of sequestra in inflammatory diseases of bone was a consequence of its hardness. Prof. Drennan then went on to consider some of the dystrophic diseases of bones. He outlined the principal structural changes in osteitis fibrosa due to parathyroid over-activity, and emphasised that no special histological type of parathyroid overgrowth could be incriminated. The structural changes in osteitis deformans were very similar to those in osteitis fibrosa, but with bone deposition predominating over bone resorption; and there was no definite evidence that osteitis deformans was an endocrine disturbance. Regarding the reactions of bone to invading tumours, dural meningioma provided an interesting instance, exemplified by a remarkable case which he described. The so-called "benign" giant-cell tumour of bone had better shed its benevolent title, for it might yield metastases. In a recently observed case of tumour of the humerus, biopsy sections had the structure of the so-called "benign" giant-celled growth; but, after amputation, more thorough sectioning of the growth revealed also areas of osteogenic type, and the patient subsequently died with large pulmonary metastases. Prof. Drennan concluded his address with an account of two cases of plasmocytoma of the spine.

Prof. MACCALLUM spoke of the views of Leriche and Policard on osteogenesis, and maintained that the evidence in their favour was unsatisfactory. He also said that the mechanical efficiency of bone might depend not only on its calcium content but on the quality of the matrix.

Dr. K. INGLIS (Sydney) mentioned a case like that described by the president, in which an osteogenic sarcoma showed areas resembling giant-cell tumour. He asked whether Prof. Drennan thought that osteoclasts were essential to bone resorption. He also mentioned the occurrence of heterotopic bone in the liver of a dog exposed to X rays.

Dr. KING described the metaplastic changes in the joint tissues and bones of Charcot's joints; and also the development of metaplastic bone in the walls of arteries. From a study of bone sarcomas he believed that many of these contained hæmopoietic tissue as an integral part of the growths.

Dr. WILLIS said that bony metaplasia in connective tissues showed that even in the adult body the tissues had not completely lost that plasticity which was characteristic of the early embryo. Since

connective tissue could become bone, and vice versa, it was probable that reversible osteoblast-fibroblast transformations were of great importance in bone pathology.

Dr. DUHIG mentioned a case of sarcoma supervening on osteitis deformans, and asked how common this change was.

Dr. WRIGHT said that Leriche and Policard's views did not accord well with his observation that in limbs which were the seat of arteriovenous aneurysms, no abnormalities were found in the bones in spite of the altered circulatory state.

The PRESIDENT, in reply, agreed with Dr. Willis that osteoblasts and fibroblasts need not be looked upon as rigidly specific types of cells. In answer to the question of Dr. Inglis, he said that bone resorption was possible without osteoclasts, and the factors determining the numbers of these cells were obscure. To Dr. Duhig he said he did not know how often sarcoma supervened on osteitis deformans, but this finding was certainly uncommon.

Leukaemic Infiltrations and Teratomata

Leukaemic infiltrations was the subject of a brief paper by Prof. J. B. CLELAND (Adelaide), who described several cases in which post-mortem study revealed unsuspected leukaemic infiltrations of heart, kidneys, pancreas, and other organs. He emphasised the difficulty of differentiating sharply between leukaemias and lymphosarcomatosis which might yield identical histological appearances in various viscera, as might also acute Hodgkin's disease.

Neural Components in Teratomata.—Dr. WILLIS illustrated this subject by a series of lantern slides. Teratomas when adequately examined were found to contain neural tissues very frequently—in 18 of 22 specimens studied by the speaker. These tissues took all possible forms, including immature neuro-epithelial tubules, differentiating spongioblastic tissue, fully differentiated neuroglial areas with astrocytes which stained typically with Cajal's gold sublimate, nerve-cells in central nervous tissue, ependymal cavities, choroid plexus, peripheral ganglia, nerve bundles, and pacinian corpuscles.

SECTION OF SURGERY

ADVANCES in our knowledge of hydatid disease during the twentieth century was the subject of a discussion at this section opened by Prof. HAROLD R. DEW (Sydney).

Hydatid Disease

In Australia, he said, the disease first came into prominence in the 'sixties, and reached its peak incidence in the 'nineties. The clinicians of this time, meeting with the condition in all its manifestations, used their opportunities to the full and made many original observations on the clinical side. During the next thirty years, indeed, nearly all the problems of immediate practical importance were solved. To-day the disease had much diminished in frequency; it was well recognised that the commonest source of human infestation was direct contact with infected dogs, and that factors like infected water-supplies and raw vegetables were of little importance. Such infestation was readily preventable and easy to control, and its incidence should be further decreased by public health propaganda. The hydatid registry of the Royal Australasian College of Surgeons was inquiring into the incidence and distribution, but further individual research was also needed.

Prof. Dew thought that the general pathological

advances in Australia had kept abreast of those in other countries. Hydatid pathology had been revolutionised since the publications by Deve, and later by Australian and South American workers, of experiments proving that germinal elements in the form of relatively differentiated scolices derived from a fertile primary cyst could, if shed into tissues, serous cavities, or the blood stream, undergo a complete metamorphosis and become in their turn fertile secondary cysts. Clinical observation had confirmed these experiments, and the difference between primary and secondary cysts, the nature of recurrent cysts, multiple cysts, and metastatic cysts, was now appreciated. As a rule infestation occurred in childhood and the average cyst was almost as old as its host. The histogenesis of the parasite, its structure, mode of growth, and diverse pathological appearances in both man and animals were now more completely understood.

A case of alveolar hydatid, the first to be reported in Australia, which he had described in 1931, had, he said, negated the geographical argument of the dualist school, which believed that alveolar hydatid was due to a specific parasite distinct from the common form. Another important advance was the recognition of the anaphylactic nature of many symptoms of hydatid disease. It was now appreciated that symptoms were due to pressure, leakage, or infection, and he believed that the pathology and symptomatology of hepatic hydatid, its intrabiliary rupture, intraperitoneal rupture, and intrathoracic extension, were fully understood. Information was still required, however, regarding growth, distribution, and complications. Radiography had been an invaluable aid in diagnosis, and it was to the radiologist that the speaker would look for further knowledge.

The importance of the immunological tests was well known, and Prof. Dew hoped that further experimental work would throw light on their relative value and fallacies. As regards treatment, Australian surgeons had played their part in the development of radical surgical methods. Although as much was now known about hydatid as about any other disease, all possible use should be made of opportunities for further investigation—opportunities which Australia in particular could offer.

Mr. B. KILVINGTON (Melbourne) confined his remarks to calcification in hydatid cysts. At the Melbourne Hospital in the last ten years 86 per cent. of the calcified cysts found were in the liver, and he believed that this was due to the thickness of the adventitious layer in this situation. He pointed out that 46 per cent. were discovered in routine examination and presented no symptoms. The death-rate was between 5 and 10 per cent. and was always due to infection. In treatment, he accentuated the advantages of crushing the cyst, swabbing with strong formalin, and drainage. In his two cases thus treated the calcified material had soon been extruded, with subsequent closure of the sinus.

Dr. D. CARMALT-JONES (New Zealand) described the life cycle of *Tania echinococcus*. A hydatid registry, he said, had been established in New Zealand under the leadership of Sir Louis Barnett. When the registry possessed 1000 cases of hydatid disease they intended to hand over their data to the hydatid registry of the Royal Australasian College of Surgeons.

Mr. H. R. G. POATE (Sydney) discussed intrabiliary rupture of liver hydatids. He described how the common bile-duct became blocked by membrane or small cysts following erosion of the larger bile-ducts. In dealing with the diagnosis, he pointed

out that confusion often existed between this disease and gall-stone attacks. Common bile-duct drainage, he said, was advantageous for deep liver cysts communicating with the ducts.

Dr. S. C. FITZPATRICK (Hamilton, Victoria) spoke of the incidence of hydatid disease in various parts of Victoria, excluding the metropolitan area, pointing out that the disease was most prevalent where the number of sheep was greatest. In referring to liver cysts he emphasised the advantages of the sub-pleural route of approach.

Dr. K. FAIRLEY (Melbourne) confined his remarks to the immunological reactions. The precipitin test, he said, was comparable to the complement-fixation test, and had been discarded in favour of the latter, which was quantitative. This test was of value especially with complicated cysts and was the only one useful in the diagnosis of recurrent cysts. The Casoni test was helpful only in the pre-operative diagnosis of the primary cyst.

Dr. K. S. CROSS (Melbourne) showed X ray photographs of hydatid cysts. He said that localisation was more accurately determined by two views taken at right angles than by stereoscopic views.

Mr. H. B. DEVINE (Melbourne) supported by Mr. B. QUICK (Melbourne) uttered a warning against the use of formalin, and Mr. MURRAY MORTON said that the disasters which followed formalin treatment were due to the fact that Deve's technique was not carried out accurately. If this were done, in his opinion, no ill-effects would be experienced.

Sir THOMAS DUNHILL (London) paid a tribute to Deve and Dew for their work. He pointed out that the morbidity, apart from the mortality, was very great.

Prof. DEW, in reply, agreed with Mr. Kilvington in leaving calcareous cysts alone as long as possible, and with Mr. Poate in attacking the common bile-duct in most cases of liver cyst with intraduct rupture. He emphasised the importance of adhering to Deve in the use of formalin.

Surgery of the Pancreas

Mr. HAROLD UPCOTT (Hull), opening a discussion on surgery of the pancreas, said it was generally agreed that acute pancreatitis was caused by infection, the biliary tract being the usual source. He pointed out that three anatomical types were recognised, hemorrhagic, gangrenous, and suppurative. To these he added a fourth, the pancreatic oedema of Archibald and Elman. Enumerating the symptoms and signs, he laid stress on the difference between pancreatic oedema and acute pancreatitis, and also referred to the confirmatory tests used as an aid to diagnosis. The treatment was operative, external drainage of the biliary system being essential. If effusion was great the gland itself could be drained, but the drainage should not be discontinued too soon for fear of a pseudo-cyst forming. Going on to speak of chronic pancreatitis, Mr. Upcott said he believed that constant boring epigastric pain was common to most pancreatic infections and was due to the proximity of the coeliac plexus. Of the functional tests employed as an aid to diagnosis, the estimation of blood diastase was the most reliable; the diastase was increased if the ducts were obstructed, and diminished if the acini were atrophied. Treatment consisted in the establishment of biliary drainage. Pancreatic cysts Mr. Upcott divided into four types: (1) retention cysts, (2) neoplastic cysts, benign or malignant, (3) pseudo-cysts, (4) parasitic cysts. In mentioning post-operative pancreatic fistulae he suggested their dissection and implantation into the

stomach. In cases of carcinoma of the pancreas blood transfusion was useful. Surgery endeavoured to relieve the jaundice and duodenal obstruction and to remove the growth. In certain cases of hypoglycaemia attributed to excessive insulin production, local overgrowth, adenoma, or adenocarcinoma of the pancreas had been found; and if other causes of hypoglycaemia could be dismissed, pancreatic exploration was justifiable. Where no tumour was found subtotal pancreatectomy was a possibility; Mr. Upcott mentioned Graham's case, and concluded with a plea for further experimental work in this direction.

Mr. F. C. PYBUS (Newcastle-upon-Tyne) confined his remarks to acute pancreatitis, emphasising the almost constant association of pancreatitis with biliary infection. The four types of acute pancreatitis mentioned by Mr. Upcott were, he thought, rather stages in progress of the one disease than separate types. He favoured conservative treatment and subsequent drainage of any abscess formed, provided the pre-operative diagnosis was absolutely certain.

Mr. BALCOMBE QUICK (Melbourne) compared the figures of the Alfred Hospital, Melbourne, and the Johns Hopkins Hospital, Baltimore, and showed that acute pancreatitis was ten times commoner in Melbourne. He assumed that this was because the disease was more often recognised in Melbourne. He referred to the great value of the urinary diastase test for confirmation of diagnosis, and agreed with Mr. Pybus in advising delayed treatment if the diagnosis were certain.

SECTION OF MEDICINE

On Sept. 11th, Lord HORDER being in the chair, Prof. C. G. LAMBIE (Sydney) opened a discussion on

Obesity: Ætiology and Metabolism

Obesity, or excess of *dépôt fat*, was, he said, important clinically as a disfigurement, a disease, or a sign. It might produce distress, impair the sense of well-being, and even be a menace to life itself. That it shortened life was shown by insurance records. The simplest of the many formulæ given for calculating the ideal weight, although not taking into account the build of the patient, was that of Broca, where

Weight in kilos = Height in centimetres less 100.

The normal variations ranged between 15–20 per cent. above or below the calculated weight. An expression of the grade of obesity was given by dividing the actual body-weight by the ideal body-weight. The energy balance, a disturbance of which might give rise to obesity, was shown diagrammatically as follows for a male 70 kg. in weight, 170 cm. in height, aged 24 years, and performing light work:

	Calories.
Basal metabolism	1706
Activity	534
Specific dynamic action	285
Total food equivalent	2525

The energy required for activity, was much smaller than that for basal metabolism. Most persons over-eat and the possible ways of dealing with excess food were as follows:—

1. Limitation of absorption. } (Not proved
2. Elimination. } experimentally.)
3. Increased mechanical work.
4. Combustion (*luxus consumption*).
5. Storage.

He explained the anomaly of persons who ate excessively and yet remained constant in weight by *luxus consumption*, which had been proved in case of herbivora, although not in man. The amount of energy that could be disposed of by *luxus consumption* was approximately 60–65 per cent. of that required for basal metabolism, although it varied greatly in different individuals, and if it were low obesity was likely to develop from over-feeding. High sugar tolerance, if due to hyperinsulinism, would lead to obesity. Similarly low sugar tolerance caused by pituitary basophilism, abnormality of the adrenals or thymus, would also cause the excess syndrome. Lesions of the diencephalon gave increased liver glycogen and obesity.

In concluding, Prof. Lambie classified obesity as:—

- | | |
|-------------------------|-------------------------|
| A. Developmental | ? Hereditary. |
| B. Metabolic: | Hereditary or acquired. |
| Endocrine. | |
| Nervous (hypothalamic). | |
| Neuro-endocrine. | |
| C. Nutritional. | Acquired. |

Sir JAMES PURVES-STEWART (London) discussed the endocrine aspect of obesity and stressed the importance of the thyroid and pituitary glands. Pinea obesity was probably due to mechanical pressure on the pituitary gland. Pancreatic obesity due to hyperinsulinism was not frequent. Genital obesity occurred after castration or the menopause, and increase in weight during the menstrual period was noted in some fat persons. Adrenal obesity was found chiefly in women associated with subinvolution of the uterus and ovaries. Subthyroid obesity was especially marked after pregnancy; it was most obvious in the regions of the buttocks, thighs, abdominal wall, and breasts. Pituitary obesity was the most important type; it was caused by a deficiency of the basophil cells in the anterior lobe. There were grave doubts however whether the lack of hormone alone was sufficient, and it was probably a combined effect of lack of hormone and pressure on the hypothalamus. Cushing's basophil pituitary syndrome due to a mixed type of pituitary adenoma was a polygland syndrome, as it was the same as that observed in tumours of the adrenals and thymus. Obesity due to pituitary abnormalities, except tumours, were often curable, as shown by photographs of a boy who presented the typical syndrome of Fröhlich at 13 years of age, but was quite normal six years later. He had been treated with thyroid and pituitary extract.

Dr. J. H. ANDERSON (Ruthin Castle) dealt with the treatment. He stressed the importance of taking a full history and of making a complete examination so that cases could be classified according to the causative factors—endogenous, exogenous, or mixed. Where possible estimations of the basal metabolic rate, sugar tolerance, and X ray examination of the pituitary fossa should be performed. In treatment there were four lines of attack: two major, diet and exercise, and two minor, drugs and physical treatment. In most cases of obesity, diet and exercise were of paramount importance. A good reduction diet was low in carbohydrate, well supplied with protein, and strictly rationed in fat, but sufficient to carry the necessary fat-soluble vitamins. He showed the diet tables used at Ruthin Castle and stressed that the food should be varied and its bulk made up with fruit and vegetables according to the patient's inclinations. Each case must be judged on its merits, and too rapid a reduction should not be aimed at. A loss of 3 lb. per week was the average, but he

had seen as much as 12 st. lost in 8½ months. The food should be weighed in some cases and the patient should be weighed weekly and regulate the diet accordingly. Exercise should be regular and the amount should depend on the condition of the patient. Blood pressure and pulse estimations before and after exercise were useful guides in estimating this. Drugs should find their greatest use in endogenous obesity, but except in some cases due to hypothyroidism, diet and exercise were also necessary. True hypothyroid cases should not be put on reduction diets, as they stood it badly. Great care should be exercised with thyroid medication. A rise of pulse-rate of 10-15 per minute suggested overdosage. He cited two cases who had been slimming by thyroid that had led to fibrillation and oedema. Many cases of exogenous obesity were helped by gr. ½ of thyroid twice daily. Physical measures in the form of massage, electric light baths, and the Bergonié chair had little effect on the weight.

Dr. E. H. STOKES (Sydney) discussed the relationship between obesity and hypertension. He had investigated the relationship between the two conditions in his last 1000 cases in private practice. Of these 81 (43 females and 38 males) were 20 per cent. or more over-weight according to standard tables. Of the 81 patients, 18 (15 females and 3 males), i.e., 22 per cent., had systolic blood pressures of 160 mm. of mercury or more. In contrast, 6 per cent. of the non-obese group of 919 had blood pressures of the same order. Although the two groups were not strictly comparable, it appeared that hypertension occurred much more frequently in the over-weight group. Approximately half of the 18 hypertensive over-weight patients were females between the ages of 45-55. Only four cases showed evidence of endocrine disturbance. They included one acromegalic, one hypothyroid, and two diabetics. In his experience loss of weight was often followed in the obese by fall in blood pressure, and he therefore thought it not unreasonable to consider the converse could take place. He suggested that pituitary disturbance could cause both the hypertension and the obesity and concluded by saying that on present knowledge it could not be assumed that obesity was actually the cause of the hypertension present in some cases.

Prof. LAMBIE, in reply, disagreed with Sir James Purves-Stewart regarding the distribution of fat in certain endocrine cases; in his experience the distribution was very variable even in the same type of case and sometimes similar in cases of different ætiology. In determining the ætiology he paid more attention to the skin and the state of development of the genitals. Deficiency of the gonadotropic hormone probably had an indirect action. In reply to Dr. Stokes he thought that the hypertensive cases should have been correlated with sugar-tolerance estimations.

Diabetic Gangrene

Dr. A. CLARKE BEGG (Swansea) said the incidence of gangrene had increased because the longer life of the diabetic had increased the incidence of arteriosclerosis. The diagnosis was easy, but any lesion of the diabetic foot should be regarded as potential gangrene. The predisposed patient should be kept slightly below normal body-weight and the urine sugar-free. Even the slightest injuries should be avoided and the feet kept warm, dry, and clean. If dry gangrene developed it should be treated conservatively; if moist, amputation should be

undertaken without delay. The procedure for mixed types should be judged on the amount of sepsis and pain, rate of spread and constitutional disturbance. In all cases thorough treatment of the diabetic state was essential.

Dr. J. C. MATTHEWS (Liverpool) said that before amputation the circulation in the limb should be estimated at different levels by a sphygmomanometer and that a line of demarcation should not be awaited too long. Gangrene of the flaps of operation wounds in diabetics should be prevented by thorough insulin treatment.

Dr. M. D. SILBERBERG (Melbourne) stressed the importance of keeping the affected part warm and dry. By means of eusol irrigations high amputation could be avoided in some cases of moist gangrene.

Dr. KIMPSON MADDOX (Sydney) said that Pickling and Hess's method of testing circulation was simple and accurate. Coronary thrombosis was common in such cases. After operation, kidney failure was not unlikely; gas-and-oxygen was the anaesthetic of choice.

Dr. E. COOPER (Melbourne) said that powerful antiseptics, such as iodine, had caused gangrene and that bedsores must be avoided at all costs. Arterio-sclerotic fundal changes were common. Not all cases of gangrene associated with glycosuria and acetonuria were due to diabetes.

Hæmolytic Jaundice

Dr. S. O. COWEN (Melbourne) read a paper on the pathogenesis and treatment of hæmolytic jaundice. The pathogenesis, he said, was obscure, but Hayden had shown that the fundamental fault was in the erythrocytes. The familial type was common. He had seen 30 cases in the last 15 years; 17 had been in the one family. Twenty cases had been subjected to splenectomy without any deaths. The most severe cases improved rapidly and survived for many years. It was advisable to remove the spleen as soon as the diagnosis was made, because severe hæmolytic crises might cause death rapidly. The severity of the disease could best be judged by a careful history, especially the family history. Thirty-five per cent. of his cases were associated with pigment stones in the gall-bladder. If possible, when performing the splenectomy, the stones should be crushed digitally without opening the gall-bladder.

Dr. C. T. C. DE CRESPIGNY (Adelaide) asked if splenectomy prevented ulceration of the legs, which was not uncommon in these cases; and what was the treatment of the blood crises?

Dr. EVA SHIPTON (Sydney) related a case of acholuric jaundice in an elderly woman.

Dr. G. COOKE (Colombo) said that splenectomy for large spleens due to malaria was very fatal owing to pleural effusions and pneumonia.

Dr. COWEN, in reply, said that splenectomy cured leg ulcerations. Crises were treated by blood transfusions, but these might be dangerous, as fatal reactions had sometimes followed their administration.

SUNDERLAND CORPORATION MENTAL HOSPITAL.—Plans for the extension of this hospital at an estimated cost of £170,000 have been approved by the visiting committee and will be sent to the Board of Control. The extensions include a new admission block, a nurses' home, and a general hospital block, and will accommodate another 240 beds. The hospital is at present much overcrowded and, it is stated, that there are 60 beds in the hospital chapel.

INTERNATIONAL CONGRESS OF THE HISTORY OF MEDICINE

SOME forty-five nations took part in the 10th International Congress of the History of Medicine which opened in Madrid on Sept. 22nd, 1935, under the presidency of Prof. Gregorio Marañón. There were three main subjects for discussion and the greater number of papers were read in Spanish.

Arab Medicine in Spain

Dr. FIDEL FERNANDEZ (Spain) and Dr. ZAKI ALI (Geneva) described the way in which the influx of Arabian culture following the Mohammedan invasion of Spain at the beginning of the eighth century influenced medical science in Europe generally and in Spain in particular. Although dissections and autopsies were strictly forbidden, Arabian translations of Galen's "Anatomy" and a study of skeletons wherever these could be unearthed enabled the Arab physicians to devise and undertake complicated surgical operations. Thus towards the end of the tenth century a complete treatise was written on the formation of the foetus, the treatment of pregnancy, the causes of dystocia, abnormal presentations, and the technique of version. Amongst the most famous names of the Hispano-Moresque renaissance of medicine were those of Abulcasis (936-1013) and Avenzoar (1094-1162). Abulcasis was perhaps the greatest surgeon of the Arab race, and his great medico-surgical encyclopaedia "Al Tasrif" remained for long the leading text-book in all the universities. Among other things he described the technique of actual cauterisation for the control of hæmorrhage, and for fistula, liver abscess, and other conditions; tracheotomy, lithotomy, and amputations; the treatment of wounds; the problem of suppuration; fractures and dislocations; the treatment of dental and oral deformities; the treatment of hydrocele. Avenzoar, one of a long line of famous physicians, was the first to describe cancer of the stomach, pericarditis, abscess of the pericardium, peritoneal and mediastinal abscess (from which he himself suffered), pharyngeal paralysis, otitis media, and the nervous complications of Pott's disease.

Dr. ASHER BLOOM (Cairo) showed that the osteology of Abulcasis was really derived from a part of the Talmud, known as "Michna," an ancient Hebrew compilation of the second century, in which a detailed description is given of the 248 bones of the human body. In any case it is certain that "by the tenth century the Moslems had brought to Spain a vast accumulation of Greek philosophical and scientific works, with Oriental elements added." In the twelfth century the Hispano-Jewish physician Maimonides was an outstanding figure. Personal physician to the Court of the Sultan Saladin, he was a fervent advocate of preventive measures—personal hygiene and diet—rather than drugs in the maintenance of health. The function of medical knowledge was, in his own words, "to teach humanity the causes of ill-health, the correct dietetic hygiene . . . how to prolong life, and how to avoid disease."

Dr. PIETRO CAPPARONI (Italy) described the work of Ibn-al-Baitar (thirteenth century), whose famous botanical treatise "Simplicia" constituted a remarkably complete materia medica of his day and led to great progress in therapeutics and pharmacology.

Medicine During the Colonisation of America

Prof. AUGUSTO DA SILVA CARVALHO (Lisbon) confined himself to a review of Portuguese America,

Brazil, from the time of its discovery by Pedro Cabral in 1500. The diseases encountered by the colonists included heat-stroke; virulent malaria of various types which frequently killed its victims in two or three days; goitre; parasitic infections; tetanus; typhoid, paratyphoid, and typhus; grippal influenza which decimated the country towards the end of the sixteenth century; pneumonia; scurvy; beri-beri; dysentery; syphilis; yaws; tropical anaemia; tuberculosis; small-pox; scarlet fever; yellow fever. Medical assistance was extremely scanty and precarious for a long time over the whole of South America, and for many years was almost exclusively represented by empiricists and charlatans who flocked to the country and often made large fortunes there. Many of the American Indians, however, were skilled in the lore of herbal remedies, applying various roots, barks, flowers, leaves, seeds, and fruits for the successful treatment of disease. Our knowledge of many vegetable drugs, later included in our own materia medica, is due to these early pioneers. Moreover, in the sixteenth century missionaries, especially among the Jesuits and members of the secular clergy, possessed some knowledge of medicine acquired in convents and hospitals and by the reading of books in the monastic libraries, this knowledge giving them an enormous prestige in their work of colonising and proselytising.

Dr. EMILY EMMART (Johns Hopkins) gave a description of the Badianus manuscript, a sixteenth century Mexican herbal, written in Aztec and Latin, this book representing not only Aztec medical treatments which existed at the time of the Conquest, but also the earliest academic instruction in medicine in America.—Dr. M. A. VAN ANDEL (Holland) gave an account of William Piso, physician to the Dutch West Indian Company in Brazil between 1636 and 1644. Piso was the author of a learned encyclopaedia of the natural history of Brazil, with chapters on its diseases, their origin and treatment; but his outstanding contribution to medical science is his description of dysentery and its cure by the ipecacuanha root, a specific whose virtues he learnt from the Indians who employed it as an emetic in cases of poisoning and as an astringent in chronic diarrhoea. Dr. van Anandel showed that the merit of introducing emetine into the materia medica should be attributed to Piso rather than to Garnier and Helvetius.

Medical Folk-lore

Prof. LAIGNEL-LAVASTINE (Paris), in a general introduction, said that medical folk-lore had a double interest, theoretical and practical. Modern therapeutic investigations had often confirmed the value of substances employed in popular medicine. Medical folk-lore could be classified in three groups: ethnological mutilations; magical and religious practices; and popular medicine. A study of this kind involved both psychological and social factors, of which the former were genetic and included essentially instinct, analogy, and animism with its derivatives.

Dr. J. D. COMRIE (Edinburgh), discussing the medical folk-lore of Scotland, said that one of the chief methods of healing in pre-Christian days was by bathing in or drinking from wells in which a spirit was believed to reside. Christian missionaries coming to Scotland in the seventh century and finding this form of healing firmly fixed among the people, blessed the wells, giving them the names of various saints, and some of these wells are still used for healing purposes. Balls of rock crystal and other stones with a reputation for healing properties are preserved in various Scottish families. Lists

of remedies used among the Scottish peasantry were published in the seventeenth and eighteenth centuries, some of these remedies, made from plants, appearing to be natural and salutary, but many were extremely disgusting.

Prof. VICTOR GOMOI (Rumania) included under the name "medical folk-lore" the whole of popular sanitary science—a science which was reflected in popular beliefs, habits, superstitions, prayers, incantations, witchcraft, charms, and various medical and surgical practices. He insisted that if more attention had in the past been paid to medical folk-lore, medicine would have avoided many useless deviations in its evolution, and scientific medicine would have reached a more advanced point than it has done to-day. Popular science in the Balkan countries has given to scientific medicine many priceless therapeutic elements: baths, variolisation (ancestor of vaccinothrapy and even of vaccination itself), cupping, and a vast number of vegetable and other remedies (opium, squill, petroleum, &c.) to which "medical science" has done no more than verify their action by experiment and perfect their mode of use.

Dr. P. STOLANOFF (Bulgaria) described the popular beliefs of his country in regard to various diseases, their cause and treatment, with the forms under which the medicinal plants are administered in each case.

Prof. SÜHEYL ÜNVER gave a similar account of popular beliefs in Turkey, and other speakers for Switzerland, Scandinavia, and Italy.

This section was followed by papers on the history of medicine and medical sociology contributed by Dr. HENRY SIEGIST (Johns Hopkins University) and others. An exhibit of the Wellcome Historical Medical Museum included illustrations of Arabian surgical instruments from the early fourteenth century; MSS. of Abulcasis; examples and replicas of other early medical MSS.; objects of historical ophthalmology, with a section devoted to the evolution of spectacles. Several dioramas were shown, including a view of the Hospital of Santa Cruz at Toledo, as it appeared in the sixteenth century.

Visits were arranged to a large number of institutions of scientific, historic, artistic, or archaeological interest, including a day at Toledo.

AUSTRALASIA

(FROM OUR OWN CORRESPONDENT)

THE VISITORS TO MELBOURNE

THE 103rd annual meeting of the British Medical Association, the first meeting of its kind in the Southern Hemisphere, has been attended not only by many world-famous medical men and women from Great Britain, but by distinguished representatives of medicine from Holland, China, Japan, India, Ceylon, and most parts of the British Empire. The contacts brought about by such a gathering will be of value to all, whilst the election of an Australian doctor to the presidency is much appreciated here.

Most of the visitors from Great Britain travelled across America; one party crossed Canada, the other the United States, the latter spending two days in New York and one in Washington, with shorter halts at Chicago, Albuquerque (New Mexico), and Los Angeles. A special air-conditioned train was made available for the party on this transcontinental

journey. The *Aorangi*, with the northern party on board, was diverted to San Francisco to pick up the southern party, and enjoyable days were spent at Honolulu and Suva. At Suva, a special display of fire-walking was given and great interest was taken in the medical school for training native doctors. The party, which numbered 250, arrived at Auckland in New Zealand on Sept. 2nd. Many took the opportunity to visit Rotorua, where they received enthusiastic civic and Maori welcomes. The *Aorangi* reached Sydney on Sept. 6th, when a civic welcome was given and the party were entertained at luncheon by the New South Wales branch of the B.M.A., and left next day for Melbourne. Large numbers of members were brought also from New Zealand by the *Wanganella*, and many arrived via Suez. The attendance at the congress of members and their families is estimated at between 3000 and 4000.

It may be mentioned here that at the annual dinner Mr. H. S. Souttar, chairman of the representative body, suggested as a permanent memorial of the visit the inauguration of a federal medical research endowment fund in Australia. It was announced later in the week that the Federal Government, acting on this suggestion, are taking steps to form an Australian Medical Research Council.

There can be no doubt about the success of the congress, which reflects the greatest credit, not only upon the central organisation in London, but particularly on the members of the Victorian branch of the Association, who have been untiring in their efforts.

PARIS

(FROM OUR OWN CORRESPONDENT)

A NATIONAL CENSUS OF DOCTORS AND DENTISTS

A FEW months ago the Commission de l'Hygiène de la Chambre des Députés, of which Dr. Nast is a member, issued a report on the need for a national census of the doctors and dentists legally qualified to practise in France, and this recommendation has now been incorporated in what is commonly known as the Nast law of July 26th, 1935. Every properly qualified doctor and dentist practising in France will have to show his or her diplomas before Jan. 27th, 1936, and for the bona-fide practitioners who have lost their papers this law will be a source of some temporary inconvenience. But the people who will and who are meant to suffer most are the unqualified practitioners who have hitherto succeeded in posing as doctors and dentists, thanks to the lack of a central national register.

FRAUDULENT MEDICAL CERTIFICATES

Another new legal enactment concerns the medical practitioner who in the past has promoted malingerer by the issue of misleading medical certificates. In a letter dated August 8th, 1935, addressed by Monsieur Laval to the President of the Republic, it is pointed out that, in the present state of the law, the authorities are unable to bring before a court of justice the doctor who issues misleading medical certificates enabling their recipients to claim undeserved pensions or grants. Accordingly, Monsieur Laval has included among his emergency decrees a modification of the first paragraph of Article 160 of the Penal Code, which henceforth reads: "Every doctor, surgeon or other medical officer of health who, to favour someone, certifies untruthfully to diseases qualifying for dispensation from public service or for the receipt of a pension

or grant from the State or a public body, shall be punished with imprisonment for a minimum of one year and a maximum of three years." This decree will have to be ratified by Parliament, but whatever its ultimate fate, it should have a quite definitely inhibitory action on the light-hearted dispensing of documents certifying to the reality of unreal diseases.

CONTROL OF MEASLES

A recent epidemic of measles in Saint-Étienne, a French town of some 200,000 inhabitants, is the subject of an informative study in the *Revue d'Hygiène et de Médecine Préventive* for October. The author, Dr. Poulain, the town's medical officer of health, has collected and classified the records concerning measles in Saint-Étienne since 1891, and he has found that in all but 5 of the 44 years under review there have been outbreaks of the disease. Their average duration was nine months, and after attaining their maximum in March and April they usually petered out in July or August. Those of greatest severity were usually seen at three-year intervals. Since 1891 there have not been two successive years without an outbreak of measles in Saint-Étienne, and throughout this period and until 1930 there has been little change in the mortality from its pulmonary complications. There was thus a useful and reliable background by which to judge the efficacy of the measures Dr. Poulain put into force in the epidemic which he describes, and which began in November, 1933, and lasted during the first seven months of 1934.

The first to suffer were some 70 soldiers of the garrison. The deaths of 7 of them created a stir which facilitated the educational and administrative measures Dr. Poulain proceeded to promote. His two main principles were as far as possible to prevent children under the age of two from contracting measles and to avoid its complications—notably those of the respiratory tract—in children over this age. For children under two he sought to prevent infection by discouraging their attendance at welfare centres and similar institutions designed for their welfare but liable to become foci of disease. For children over the age of two, he considered it useless to close the schools, but he made the parents realise that a child with coryza should at once be kept at home. For children of all ages his advice was that hospitals should be given a wide berth. Such festivities as public Christmas tree parties were suppressed. The serum of convalescents was available in quite inadequate quantities, for though 17 of the aforementioned soldiers served as donors between the seventh and ninth day of desquamation, attempts to induce the civilian population to serve in the same capacity proved remarkably futile. But the serum (what there was of it) proved a great success, no complication such as bronchitis being observed in any of the cases thus treated even when they were given the serum comparatively late. What was, however, most impressive was the remarkable fall in the mortality of this epidemic compared with that of earlier outbreaks. The mortality from the complications of the respiratory tract was 11.3 per thousand as compared with 32.3 in other years of severe epidemics; indeed it was even less than the corresponding mortality in the years without any definite epidemic of measles. This achievement is attributable to the combination of measures adopted and not to any one of them in particular; and credit should be given to the lay press for its success in transmitting instructions to parents to keep their children at home when the weather was too cold

for them. Dr. Poulain concludes with the calculation that though his measures were simple and improvised, they saved at least 50 lives in infancy, and as many others between the ages of one and five years.

ANTHRAX

Anthrax is notifiable in France when it develops under industrial conditions but not otherwise, and the available figures give a false impression of its rarity. Even so, there seems to be no tendency towards its abatement; the annual average for the 24 years 1910-33 is 43, with a case-mortality of 11.5 per cent. Dr. E. Agasse-Lafont (*Presse méd.*, August 14th, 1935, p. 1291) reports that the Commission d'Hygiène Industrielle has been discussing the course to be recommended when a wound is suspected, without being convicted, of being infected with anthrax. Should an aseptic dressing be applied, or should antiseptics, with tincture of iodine, be used? The evidence in favour of the tincture of iodine ritual was singularly unconvincing; and if the inclusion of iodine in standard first-aid outfits recommended to industry by the Minister of Labour was still upheld, it seems to have been countenanced as a gesture rather than for any more material motive. Asked by the Ministry to give his opinion on the subject, Dr. Perrin, with an experience of more than 300 cases, wrote: "At the Saint-Denis Hospital, as soon as anthrax is diagnosed, treatment with serum is instituted, and we can say that at present deaths are almost rarities. Painting with tincture of iodine is as useless as it is ineffective." The instructions issued by the Pasteur Institute with its serum state that "local treatment (cauterisation, injection of iodine) may be dispensed with when serum is given"; and when asked to give an opinion on this subject, the sero-therapeutic service of the Institute replied last December with Delphic diplomacy that "local treatment cannot be injurious. The doctor in charge must decide whether it is necessary or not." Dr. Agasse-Lafont endorses this formula as a faithful representation of our knowledge, and goes on to emphasise the supreme value of general treatment, notably serotherapy.

ADVANCES AND THEIR APPLICATION

A subject raised by Dr. Batier, of Strasbourg, last year is of perennial interest: how best may we introduce new forms of treatment to the medical profession so that their benefits are soon gained by the public? The alternative policies he recognised were the dictatorial and the persuasive. The first conceives of the public health authorities as a kind of link between the more advanced members of the profession and those whom character or circumstances cause to lag behind; the duty of these authorities would be to "recommend," in the administrative sense, whatever measures were approved by the élite of the profession. Batier provided a telling illustration of his meaning when he referred to artificial pneumothorax—advocated for years, and even decades, by the expert but ignored by the rank and file. And though it is true that the consultant sometimes shows obtuseness where the general practitioner has a quick grasp of realities, there have certainly been occasions when much time had been lost in making use of useful advances. More hopeful, however, than Batier's dictatorial solution is his alternative: teach the younger men, and in due course their therapeutic achievements will compel emulation by the older generation. Perhaps. This happy vision of the young teaching the old must carry conviction, at any rate to the young.

POST-GRADUATE LECTURES

Our series of summaries of lectures given at the recent post-graduate courses in London teaching schools is continued this week. Dr. Lightwood, Dr. Lloyd, and Mr. Tudor Edwards all spoke at Westminster Hospital, the addresses of the two last being delivered consecutively.

SOME POINTS IN THE DIAGNOSIS AND TREATMENT OF DISEASES IN CHILDHOOD

(DR. REGINALD LIGHTWOOD)

General approach to the patient.—On first seeing the patient we should take the history; then make our examination and complete it before doing the real thinking which leads to diagnosis. Parents hang attentively on the questions the doctor puts and attach great importance both to what we ask and our method of asking it. It is a mistake to adopt a menacing, third-degree, Scotland Yard attitude. Always welcome a child patient with a smile; he is meeting somebody strange and is apprehensive. A children's doctor must not find it painful to smile and to be friendly to his patients. The child who screams down the consulting-room is usually a spoilt child, but never tell the mother that her child is spoilt, or you will be unlikely to see her again. Take her aside and then lead her spontaneously to suggest that her child is a bit spoilt; this can be done with a little tact. Never criticise her in front of the child; it is bad for home discipline.

History taking.—The secret of success is to adopt a routine of questions, which needs a little trouble before it becomes second nature. Intelligent questions, besides giving the information you want, will favourably impress the mother with your competence. For instance, in the case of an infant, ask whether full-term or premature; the weight at birth; the weekly gain; the feed; the interval between feeds, and whether both breasts are used at each feed or alternately; whether the baby takes the breast well or interrupts his feed for any purpose such as failure to breathe through the nose; whether he brings up wind successfully after feeding. Then ask about the stools; how often passed; are they formed; what is their consistency and colour; is there any flatus? Ask the questions quickly enough so as not to waste time, but not so quickly as to muddle the mother.

In dealing with a child I treat him almost as if he were grown-up and never patronise or talk down to him. It is important to get his confidence so that he will not back away and have to be pursued round the consulting-room. Come to the examination gradually. After a general glance, start by a friendly stroking of the abdomen, then palpate each part of it in a definite order. I always start with the left iliac region, then the left hypochondrium, and so, anti-clockwise, to the right iliac fossa. Children do not always like percussion and the stethoscope, and these should be used gently and tactfully. Always complete your examination, including the fauces and urine, and do not omit any part of it because the diagnosis already seems clear.

Value of the sleeping pulse-rate.—The sleeping pulse-rate, plotted on the same chart as the day pulse-rate, is essential in the examination of certain cases of heart-trouble. In the normal child it should be 10 to 15 beats slower than the day pulse. In

severe rheumatic carditis the two rates approximate and are both faster than in health. The sleeping pulse-rate will give an idea of when the patient can be allowed to get up; for when the nocturnal tracing retrains again from the day tracing, assuming the normal interval, and the tachycardia is disappearing, then there is definite clinical improvement. Similarly, narrowing of the interval and nocturnal tachycardia give warning of a relapse. The sedimentation-rate is another useful indication of when carditis ceases to be an active inflammatory process, for with improvement it becomes less and then returns to normal, more or less in step with the sleeping pulse. The sedimentation-rate is also raised in articular rheumatism and infection of the tonsils, nephritis and pneumonia, and so forth, but, curiously enough, not in chloria.

Nervous tachycardia.—Some nervous children complain of vague pains, are easily tired and pale, show tachycardia, thumping of the first count at the apex, and a suspicion of a systolic bruit. In this way rheumatism may be simulated. The sleeping pulse-rate will give the diagnosis between early rheumatic carditis and this nervous tachycardia, for in sleep the nervous influences are not at work and the pulse-rate is therefore normal. The child who is suffering from tachycardia and neurovascular debility is usually brought to the doctor because he is pale; the cause of this pallor is often fear or fatigue. After a few minutes in front of the fire with a picture book his colour often recovers. The pallor of anaemia does not disappear in this way. In this neurovascular syndrome there may be postural albuminuria at night and a day specimen should be taken. Dyspepsia is also a common complaint. In treatment a régime should be sketched for the parents; fatigue should be avoided but stimulating exercise encouraged. Cold or cool baths are better than hot ones. The child should not be taken away from school, except possibly for the afternoon if conditions make for too much strain. One hour's rest during the day, lying down, is important. As a tonic, a mixture of hydrochloric acid, gentian, and nux vomica may be given, but not iron.

Anaemia.—In anaemia the pallor is best judged from that of the palms, which can be matched with those of the physician. A guiding principle in the treatment of anaemia depends on the colour-index; if it is low, iron will probably be useful; but not if it is high. Iron-deficiency is, however, by far the commonest cause of anaemia. Reasonably big doses of iron are required; ordinary reduced iron mixed with sugar is invaluable. Even a premature infant can take it, and the dose for a six months' child is gr. $\frac{1}{2}$ and for infants over a year grs. 2. The saccharated sugar of iron is useful, as is the proprietary preparation Ferrodic. Choose ferrous preparations and avoid organic compounds.

Drug tolerance.—Infants tolerate some drugs very well, especially belladonna. This for instance is a sheet anchor in nervous enuresis, in which some kind of homely suggestion also helps by increasing confidence. The commencing dose of belladonna is 5 minims of the tincture, increasing to 10 and then to 15 minims until the enuresis is controlled or symptoms of intolerance appear. If this drug is successful, continue it for two months and then diminish it gradually. Chloral is the safest and best drug for infants with convulsions; they are tolerant to it and as a single dose, grs. 5 can be given per rectum. Before starting to treat epilepsy the physician should

make sure of his diagnosis and that the fits are regularly recurring. Potassium bromide, grs. 5 three times a day, should be continued without intermission until the next fit, when it should be increased, and so on until no more fits are occurring. The dose ascertained in this way is continued for two years. The bromides of course are not always successful in epilepsy, but should receive first trial.

MEDICAL TREATMENT OF PULMONARY TUBERCULOSIS

(DR. W. E. LLOYD)

THE successful treatment of pulmonary tuberculosis depends upon one factor more than any other, and that is early diagnosis. Although the outlook for the tuberculous patient has improved greatly since the wider use of methods aimed at resting the diseased lung by collapse therapy, I think that further improvement depends upon earlier diagnosis.

Pulmonary tuberculosis begins in the majority of cases as a localised lesion in one area of one lung, and it should be our aim to attempt its diagnosis in this stage. Unfortunately, however, such localised disease is often so silent and insidious in its development that any disturbance of health to which it may give rise is so trivial as to pass unnoticed by the patient. How then can more early cases be diagnosed? This can be done by regarding every patient, especially a young adult, with symptoms of chest disease as a possible case of tuberculosis. Such a case calls for the most complete investigation. A detailed history may reveal important facts—e.g., contact in childhood with a case of tuberculosis, or a history of pleurisy. Hæmoptysis is a symptom which calls for special mention, for it is often the first indication of tuberculosis. A patient who coughs up blood rarely fails to consult a doctor, and it is therefore not surprising that many cases owe their early diagnosis to the occurrence of hæmoptysis. Physical examination of the chest usually proves negative in the early case. The patient should be encouraged to produce a specimen of sputum for examination for the presence of tubercle bacilli. The most important investigation of the suspected early case is a good radiogram of the chest, and there is much truth in the remark that the earliest lesion of pulmonary tuberculosis is seen and not heard. The question is often asked if early tuberculosis can be diagnosed by radiography alone. I think the answer is yes if the complete data of the case are considered in conjunction with the radiogram. Unfortunately, by the time an X ray film has been taken, the case can no longer be called an early one; but by insisting on radiography of the chest for every patient with chest symptoms, as soon as these develop, more early cases will be diagnosed.

Having found the early case, what are the principles which govern its treatment? The pathogenesis of tuberculosis in a young adult is obscure and little is known as to its precise nature. The development and increase of a tuberculous lesion in the body indicates that the defensive processes have failed, and it is hoped failed temporarily. The treatment of such a case is directed to the general health of the patient with the object of increasing immunity, and the best way to do this is by advising a period of rest in bed. Treatment by this means is the basis of the successful treatment of the early case.

As soon as pulmonary tuberculosis has been diagnosed it is important to explain to the patient that adequate treatment of the early stage of the disease

is essential and the coöperation of the patient must be obtained. At least two months' rest in bed should be advised, and this should be commenced as soon as possible after the diagnosis has been made. Rest in bed calls for adequate nursing facilities and more hospital or sanatorium beds are necessary for the bed treatment of the early case. Signs of toxæmia, as indicated by raised temperature and pulse-rates, usually soon disappear, and estimation of the blood sedimentation-rate at frequent intervals is a helpful guide in determining the degree of toxæmia present. If toxæmia persists in spite of rest in bed (and this to be efficient must be rigidly enforced), the question of other methods to help the patient should be considered. Of these the most important is that of resting the affected lung by artificial pneumothorax. In every case of unilateral tuberculosis this method of treatment must be discussed. Opinions differ as to the best time to commence collapsing the lung. There are many authorities who advocate that a pneumothorax should be attempted as soon as the diagnosis of unilateral tuberculosis has been made, even if signs of toxæmia are absent. I do not share this view, and in the early case I think it advisable to concentrate on general treatment rather than on the local condition of the lung, and recommend (as indicated above) at least two months' rest in bed. At the end of this time, another radiogram should be taken and compared carefully with the previous film. Often definite improvement will be observed. The patient is then allowed out of bed for gradually increasing periods until at the end of another month he is ready for the next stage in treatment—namely, sanatorium régime. Here the arrest of the disease as shown by radiography is subjected to the test of increasing exercise, and the sanatorium should be regarded chiefly as a place where the patient's reaction to a more active life can be watched accurately. In many of these early cases he is well enough to return to work after six months' treatment, but the importance of supervision of the patient after leaving the sanatorium cannot be over-emphasised. The case should be kept under observation for at least two years and control radiograms taken every three months. Such is the routine treatment of the early case in which the original lesion had improved radiologically after two months' rest in bed. If in spite of rest there has been no such improvement, an artificial pneumothorax should be attempted. The above remarks apply only to the patient in whom the disease is localised to a limited area of one lung. The next type of case to be considered is the one in which there is extensive unilateral disease, and this forms a much larger group than the type so far described. Rest in bed, together with artificial pneumothorax, is the ideal method of treatment. In these cases the best results of pneumothorax are obtained after a preliminary period of three or four weeks' absolute rest. As a rule, there will be evidence of cavitation in the radiogram. A pneumothorax may not collapse a thick-walled cavity, and the case with an uncollapsed cavity in a partially collapsed lung calls for the coöperation of the surgeon. Good results may be obtained by cauterisation of adhesions or by paralysis of the diaphragm after evulsion of the phrenic nerve.

If one lung is extensively infiltrated by tuberculosis it is more than probable that the other lung is not entirely free of disease. In the early days of pneumothorax treatment it was not considered advisable to attempt it if there was any disease in the other lung. This depends upon the extent and

type of disease in that lung. If the radiogram shows apical disease with evidence of fibrosis this is not a contra-indication to collapse the badly affected lung.

The success of pneumothorax treatment depends largely upon the care with which the case is supervised after the patient has left the sanatorium and is attending for refills. X ray screening of the chest is necessary before each refill. By this means it is possible to maintain an almost constant degree of collapse and displacement of the mediastinum is avoided. In this way also will early collections of fluid in the pneumothorax cavity be diagnosed. Fluid occurs at some time or other, in small or large amounts, in nearly every case. Fluid which remains sterile and free of tubercle bacilli may be left unless it is so large in amount as to cause dyspnoea when it should be replaced by air. Fluid, however, may become purulent and a pyopneumothorax gives rise to the greatest anxiety. Fortunately it is uncommon, but it must be kept in mind as one of the complications of pneumothorax treatment. Another great disappointment is the case which has done well after treatment by this method and in which a fresh area of disease develops in the other lung. This development calls for further rest in bed with the object of preventing the new lesion from spreading. The value of sanocrysin or other gold preparation has been proved in such a case but it may be necessary to collapse the recently affected lung and allow the other lung to re-expand gradually. These points are mentioned to indicate the importance of accurate supervision of pneumothorax treatment. The general health of the patient must also be watched closely, and the amount of rest necessary during the twenty-four hours assessed according to the patient's condition.

It should always be remembered that pneumothorax treatment may not be possible owing to the presence of pleural adhesions, and it will save much disappointment if the patient is told that the treatment may not be successful. If pneumothorax is impossible and the disease is unilateral the question of surgical methods of collapse, including apicolysis and thoracoplasty, should be considered.

The next type of case to be discussed is the one in which there is bilateral disease when first diagnosed. Rest in bed is again the most important method of treatment and is governed by the degree of toxæmia present. If the latter persists the administration of gold salts is worthy of trial, but only if there is no evidence of enteritis and the urine is free of albumin. Small intravenous doses of 0.1 g. sanocrysin given at weekly intervals over an extended period is the best method of administration. Some authorities advise the use of bilateral artificial pneumothorax in these cases but the results are disappointing. The results of treatment by prolonged rest in bed often exceed expectations and an attitude of optimism towards the patient is justified.

Finally, the principles of treatment of senile tuberculosis. In late life toxæmia is usually absent, and treatment should be on general lines. The dyspnoea which is often a conspicuous feature of these cases calls for a life of restricted activities. Active treatment in the form of collapse therapy is not to be recommended. The condition may be associated with chronic bronchitis and emphysema, and the tuberculous basis of the disease may be overlooked until the sputum is examined. From the public health point of view these cases are a fertile source of infection and great care must be taken to prevent spread of infection to younger members of the household.

In conclusion, I should like to repeat that the successful treatment of pulmonary tuberculosis depends upon its early recognition; and as facilities for radiological examination of the chest are increasing, we may hope to meet with more such cases if it is remembered that radiography is essential for early diagnosis. If the disease has become well established the question of some form of collapse therapy in conjunction with adequate rest has to be considered and the coöperation of medical and surgical treatment gives results which have undoubtedly improved the present-day outlook for the patient suffering from pulmonary tuberculosis.

SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

(MR. TUDOR EDWARDS)

THE objects of surgical treatment of pulmonary tuberculosis are rest, immobilisation, and relaxation.

They may be used to supplement measures such as artificial pneumothorax, which has already been mentioned, and which may be only partially successful or completely impossible as a result of partial or complete synthesis of the pleuræ. In the former case it is natural to expect adhesions to be present over the active areas of disease in the lung, and for this reason the value of the treatment may be restricted owing to the adhesion preventing collapse of an underlying cavity. If these have been present for some time it is advisable to attempt to divide them and allow the cavity to collapse. Open operation has gone out of favour and the operation is performed by introducing, under local anaesthesia, a thoracoscope into a convenient intercostal space. It will generally be found that these adhesions are more numerous than the radiogram would suggest, but those of a fibrous nature, if not too extensive, can be divided by a cautery introduced through another intercostal space. Any damage to lung will lead to complications much more serious than the condition for which the operation is undertaken, and when there is serious risk of this in the division of the band it is well to consider other measures to produce collapse of the cavity.

Phrenicectomy is a relatively simple procedure, although serious complications have been described, largely due to errors of technique. This simplicity naturally produced an excessive enthusiasm which has more recently been followed by an excessive condemnation. The value of the operation depends upon the paralysed diaphragm rising, relaxing and resting the lung. It has definite value in the control of symptoms and a less limited value in the control of the disease. As it is now often performed as a temporary procedure by crushing the main phrenic nerve and dividing the accessory branches, it possesses many of the advantages of artificial pneumothorax (A.P.). In combination with A.P. it will enable cavities, strung between apical and diaphragmatic adhesions, to collapse. Certainly it is of value at the termination of artificial pneumothorax treatment, especially for cavitary disease, where the re-expansion of the lung to the full hemithorax may be impossible and will result in fluid formation, deviation of the mediastinum to the affected side or reopening of the cavities and reactivation of the disease. In soft-walled apical cavities, which have closed after temporary phrenic interruption, the paralysis may be made permanent. In cavitation of the lower lobe closure of the cavity will often follow

the operation, particularly in cases where generalised adhesions prevent the induction of pneumothorax. In patients with extensive fibro-cavernous disease, phrenicectomy as a sole curative measure is of no value, and it is its employment in this type of disease that has led to its general condemnation by some people. Its value in hæmoptysis is debatable, and is more likely to help the patient with repeated small hæmorrhages, and it is of more danger than value in the larger hæmorrhages.

In controlling diaphragmatic pain either during or apart from pneumothorax, the operation has a distinct place. Finally, in assessing its value it is advisable to ask oneself whether it is intended to act as a curative measure or as a means of controlling symptoms and to judge the results accordingly.

Apicolysis and Thoracoplasty.—The larger surgical procedures, such as apicolysis and more particularly thoracoplasty, depend upon the patient showing evidence of some resistance to the disease, and are therefore measures which are largely reserved for the more chronic stages. They are employed particularly in patients with fibro-cavernous or fibrous disease in which there is deviation of the mediastinal structures, as seen radiologically, to the affected side. Where the collapse of the lung to be attained is a localised one such as in apicolysis or localised thoracoplasty, the condition of the "better" lung is not so important as in the complete thoracoplasty; in fact, both the localised operations can be carried out successfully bilaterally. Therefore, active disease in the "better" lung except possibly a small apical focus is usually taken as a contra-indication to complete unilateral collapse by thoracoplasty.

Laryngeal disease is not a contra-indication unless very extensive, nor is unilateral renal tuberculosis; occasionally even intestinal tuberculosis of not too severe a nature will permit the operation and clear

up with the pulmonary improvement. Technical problems I do not intend to put before you, although they are of considerable importance; but the operation of apicolysis necessitates the introduction of a foreign body—i.e., paraffin wax—into the space stripped up between the parietal pleura and the chest wall, and this, like other foreign bodies, is not always well tolerated by the tissues, and may subsequently discharge on to the surface or even into the pulmonary cavity. In general, I reserve this operation for older patients with rather more rigid chest walls, who tolerate a thoracoplasty less well.

As regards the localised apical thoracoplasties they require a much more extensive resection of the individual ribs, although the number resected is usually confined to four, five, or six.

Tuberculous Pyothorax.—Finally, a few words about tuberculous effusions. They are of two main classes: (1) where the underlying lung is unaffected and (2) where there is disease in the underlying lung. These effusions may be serous, tuberculous purulent, or tuberculous purulent with secondary pyogenic infection. The last group is the most serious and is often fatal. As regards the tuberculous purulent group without disease in the underlying lung, aspiration and lavage will often clear them up entirely by expanding the collapsed lung; if, however, this is diseased, expansion may result in reactivation, and it is advisable to perform a thoracoplasty relatively early. In the secondarily infected group, aspiration and lavage may not control the infection and intercostal drainage will be required. If the patient makes sufficient progress to justify the measure, thoracoplasty is indicated when the patient is sufficiently fit, although complete closure of the extensive pyothorax cavity is often difficult to attain.

OPENING OF THE MEDICAL SCHOOLS

THE Minister of Health spoke at Guy's Hospital last Tuesday, Sir Walter Moberly at the Royal Free Hospital on Oct. 1st, and Sir Francis Acland at the Royal Dental Hospital on the 4th. The passages printed below are extracts from their addresses to the students at the opening of the session.

THE PHYSICIAN AS MAN OF THE WORLD

By SIR KINGSLEY WOOD, P.C., M.P.

MINISTER OF HEALTH

I NEVER think of Guy's but I recall Bob Sawyer, student at Guy's, associate of the immortal Pickwick Club, and jolly good fellow. Mr. Pickwick had a high opinion of medical students. "There's a couple of Sawbones downstairs" said Sam Weller. "I am glad of it" said Mr. Pickwick. "They are fine fellows; very fine fellows; with judgments matured by observation and reflection; tastes refined by reading and study. I am very glad of it."

I am sure the world was the better for Bob Sawyer. If he leaves a lasting impression of imbibing much of his wisdom through a bottle-neck, we must remember that fiction is selective and that in the "Pickwick Papers" we see him for the most part in what might be called his unbuttoned hours of ease. Of Bob's work as a surgeon in India—which he reached via Carey-street—we know nothing,

except that he resolved "to try a little abstinence" and "has since been doing well." We remember him, not for his technical skill, though I have no doubt that was, ultimately, considerable, but as an associate of the Pickwick Club, a good companion, a man among his fellows—a theme to which I shall return.

Most of you who are now students or have just qualified will, I suppose, take up general practice, and to you I would like to address myself particularly, for two reasons, one the perfectly good democratic reason that you are the majority, and the other that, whatever the importance of ancillary services, an up-to-date and progressive corps of general practitioners is essential in our organisation for the maintenance and improvement of the public health. The health of a nation is the very basis of its well-being. A low standard of public health means waste and burden. In the fight for better health the general practitioner is in the front line.

I will not talk to you of the 'ologies—biology, physiology, bacteriology, and the rest; your teachers and indeed any one of you yourselves could do that better than I. I am but the layman looking at the doctor. Yet I am temerarious enough to think that I have something to say about your preparation for your great task. Those here who guide you, lead you, inspire you, propel you—what you will—will concentrate, and rightly, on the technical side of your art, diagnosis, therapeutics, how to set a

limb and dose a fever. But in formal lectures, clinics, and so on, time is always at their heels. They will tell you, being honest men, but they will not have time to tell you often, and they will have hardly any time at all to see that you profit by the advice, that your education should not be limited to medicine, surgery, and midwifery, that a much wider interpretation should be given to the art of medicine, that the love of man should be linked up with the love of the Art.

The doctor-priest of ancient times professed knowledge of all the mysteries of life and death. Even up to fairly recent times disease was attributed to evil spirits which had to be placated or cast out. It is not so very long since Parliament in an Act intended "for the avoiding of sorceries, witchcrafts and other inconveniences" entrusted medical registration in London to the Bishop and to the Dean of St. Paul's. To-day, however, the mystic and the empiricist have given place to the scientist. Reason reigns in the place of authority. The doctor is no longer a priest or a magician. He no longer dresses himself up, at any rate in civilised countries, in the magician's mask of the "medicine-man" or the medieval plague doctor. He has even in large measure discarded the silk topper. But an element of magic is still present, and blessed alike in works and in pocket is he who possesses it most. This remnant of magic is what has been described as the "bedside manner." I should prefer to phrase it as the human sympathy of the doctor, and it is probably more important than nine-tenths of the drugs in the materia medica.

Not that I wish to under-rate the value of some drugs at some times. Indeed, seeing that the inventor of Dover's powder was the same Thomas Dover who was largely responsible for your founder making his fortune out of the South Sea Bubble, I hope I should not be so foolish as to cast any doubt within these walls on the virtue of that particular specific. I think, however, that it is not without interest that some years ago an analysis of prescriptions in England and in Scotland showed that the Scots and the English throve to some extent on different mixtures, the Scots, incidentally, managing to get along with less of them than we did.

I have used the term human sympathy as a convenient phrase. What I want to emphasise is that a patient is a man and not a machine—a fact which it is quite easy to forget. "One man's meat is another man's poison" is true in medicine not merely as regards drug tolerance but as regards the whole attitude of the physician to his patient. You must have knowledge not only of medicine but of many men. Never forget that morbid processes may work in many different ways. Your patient's illness is related, and intimately related, to the conditions of his life, his work, his games, his diet, his friends, his mode of thought, his upbringing. To treat his illness you must be capable of understanding the whole complex which is the man. How are you to do that? By knowing much of many men. By going among men, of all kinds. By helping in affairs on local bodies. By having, acquiring, and maintaining a cultural background and not being a mere technician.

The physician, in short, must be a man of the world and of affairs. Let him learn about bones, morphology, pathological processes, and so on, and let him learn them well, but let him always remember that he is treating not a universal robot but a human being, and that his treatment will be better and more

effective the better he himself is as a human being. And just as it is important that your technical knowledge should keep pace with the times, by occasional post-graduate refresher courses as well as reading and practice, equally is it important that you should keep up the wider interests and resist, as far as you can, and for as long as you can, the narrowing process which sets in inevitably as youth travels further from the east. You have my fervent wishes for your success in the hard but noble path on which you have entered, and I hope I have your good will in mine.

THE PURPOSE OF UNIVERSITY TRAINING

By SIR WALTER MOBERLY, D.S.O., Hon.D.Litt.

CHAIRMAN OF THE UNIVERSITY GRANTS COMMITTEE

At the beginning of a new university session it seems proper to invite you to think of some of the aims of a university training, and I am going to take a very homely text:

If all the good people were clever,
And all clever people were good,
The world would be better than ever
We thought that it possibly could.

But somehow it's seldom or never
The two hit it off as they should;
For the good are so harsh to the clever
And the clever so rude to the good.

So friends let it be our endeavour
To make each by each understood;
For who can be good as the clever?
Or clever so well as the good?

The implication of those lines is that people fall into two different classes which should not be estranged from one another—indeed cannot do without one another. It is obviously the business of a university training to train the mind in the direction of cleverness. But cleverness is not enough, and goodness is not enough, and the real business of a university is to try to produce that fusion of cleverness and goodness which I should call wisdom.

In the first place, on the more intellectual side you come here to try to acquire that mastery of your profession which distinguishes the professional from the amateur. Further, you do not come merely to serve an apprenticeship to your craft; for the great characteristic of modern medicine compared with olden days is that medicine is now more securely based on science. The result of this change is that in medical matters the difference between the expert and the quack is generally understood and is regarded by the public as important, and it seems to me that in this respect the medical profession is in a much happier position than others—teaching and politics for example.

To-day, moreover, in every university and college we have such active participation in discovery and research as makes the whole of your teaching much more real. "To learn from one who is himself occupied in learning is like drinking running water. To learn from one who has already learned all he is to teach is like drinking 'the green mantle of the stagnant pool'."

On the other side it is most needful that you should widen your sphere of interest. You come to a university not merely to prepare yourself for your job but to prepare yourself for public service. Can these wider things be taught? Physics, chemistry, and medicine can be taught; but can goodness and

wisdom be taught? We are living in a crisis of civilisation, when the general movement of world affairs has got out of human control. The danger of war, for example, comes in the main from voluntary human actions. Nobody wants war; but through the absence of sufficient understanding things have got out of control of human beings. What are the universities of the world doing about it? Are they trying to turn out graduates who will have a larger portion of wisdom and judgment for the want of which the world is in danger of perishing?

But there is another difficulty. Supposing universities are paying their best attention to these tasks, we still come up against the paradox that the world does not set a very high value on the university-trained mind. If it were proposed to-morrow that the present Cabinet should be replaced by the professors of political science at the British universities, not many would be in favour of the proposal. This general opinion is based on the undoubted fact that people who have had academic training do not always make good practitioners. If university graduates are to be of use to the world they have got to consider not merely principles and the deductions from them, but the application of these things to current affairs. On the other hand there is something in the university type of thought the practical man cannot really do without; for the merely practical attitude is apt to betray us unless the world remains constantly much the same. It is for the want of the fusion of the two outlooks—the academic and the practical—that the world is largely going wrong. But if as a whole the universities are not making their proper contribution the fault, I think, lies not so much with organisation or authorities as with the students who do not always attempt to get out of university life what they ought to get.

I am sure one is missing a great deal of what university life ought to give unless one gets all the contact one can with other students: "get acquainted with your neighbour; you may like him." Unions, hostels, and the like provide opportunities for that kind of mixture. I would also advise you to take all the opportunities you can get of informal contact with members of the staff outside the lecture-room and laboratory; for I find there is nothing that so stands out in my mind as certain chances of contact with men whom it was an education to meet in an informal way. In the practice of medicine later on the human factor must be all-important; you are always meeting human beings at critical points of their lives. You must therefore learn to understand other people, to put yourselves in their places; but you must also learn judgment—to learn, that is, to try to make up your mind on something about which you are not sure. All of us must be ready to judge, in subjects which are not our own primary subjects, between the expert and the quack.

One last and most important point. I should say that any graduate who leaves a university without having made progress towards acquiring a philosophy of life has missed part of the purpose of university training. It is not the business of the university to tell you what your philosophy of life should be, but it is its business to help you to find your own. From the point of view of training for life, for producing that wisdom which is the real end and aim of a university career, the failure to attain a philosophy of life is a fatal failure. Cleverness by itself is not enough and goodness by itself is not enough.

THE DENTIST'S MIND AND FINGERS

By SIR FRANCIS DYKE ACLAND, Bt., P.C., M.P.
CHAIRMAN OF THE DENTAL BOARD OF THE UNITED KINGDOM

I NEVER see students unless I attend the opening of a dental school, or a new department of one to which the Dental Board have contributed. But I see a good many of them in the stage just before they become students—or don't, as the case may be, the event depending on a short conversation I have with them at the offices of the Dental Board, with our treasurers listening and helping me in very difficult decisions. And if I try to tell you what, in a short ten minutes, I try to find, it may indicate the sort of qualities which seem to me likely to make a student a valuable member of the profession.

"Character, keenness, individuality" express it fairly well. I know that many of you have had to cram for the Higher Certificate examination, one of the most pestilent hindrances to good secondary education which we have, and have hardly had time to develop any interests except in the subjects contained in the syllabuses which that examination covers. And we try to make allowances for that. But one wants to find something, and it is difficult to describe it more closely than in the three words I have used. But this conversation, which I will give verbatim from one which occurred a fortnight ago, illustrates the absence of the qualities I look for, and it may show you why I think they help to make a good dentist. They certainly help him to get a start on his professional training when he needs assistance from the Dental Board.

ME: I notice you passed your Chemistry in May; what have you been doing since?—VICTIM: I've been at home.

Yes, but have you done any biology, or made any sort of contact with professional work?—No.

Not been to the workroom of any dentist to see the sort of thing you may be doing later on?—No.

Well, what have you been doing? Have you any hobbies?—I did a little fretwork.

Yes, I know, we all catch fretwork like whooping-cough when we are about thirteen; anything else? Have you done any carpentry, or wood-carving, or cabinet-making?—No.

Any making of models or wireless?—No.

Can you tell me the names of any books you've ever read?—I don't think so.

Well, what have you been doing? Have you played any games?—Tennis.

Very well, anything else, since May?—I'm keen on gardening.

Splendid; tell me the names of three sorts of potatoes.—Only flower-gardening.

Good; tell me the name of any sort of rose.—I'm afraid I can't; I just like to keep the garden bright.

And after he has faded away one notices that the family consists of himself and four sisters, which perhaps explains things. And he doesn't get a bursary.

A dentist must be more than a hewer of vulcanite and a drawer of teeth; he must be alive, and alive of course to his finger-tips. But I don't believe that a man's finger-tips can be really alive unless he is alive in himself. That line of Terence which brought down the Roman theatre twenty-one centuries ago "*nihil humanum alienum a me puto*" might well be a motto for the profession. I translate it, roughly, as "I'm keen on every blooming thing." We none of us know what we are really on this world for; but I hazard the suggestion that our minds and bodies and hands were given us to be used. You

only get expert use of anything by practice; and 16 hours a day isn't too long to be practising either mind or body, or both together, as you will find you have to do if you are to make good as practitioners.

Let me tell you a secret. I think very little of my mind, for I don't really trust it, but I think a great deal of my fingers. I have to use my mind, such as it is, and I get the chance to use my fingers hardly ever. But I would take on any of you at putting that tiny brass wire back into a hypodermic needle, size 18, first shot. Not only because I had to do it, or try to, after injections of adrenaline six times a day for three years, but because (now that the asthma has departed) I still try to keep the fingers in training by practising it before I go to bed. Probably quite silly, but do you get the idea? Be proud of all the powers you have and keep them in hard training by exercise.

You have a desperate lot of work to get through here, as I well realise, but don't just do it and be satisfied. Keep your minds sharp by rubbing them up against public affairs, against books, against music, even in criticism of your lecturers and teachers. Better even, I suppose, be a jazz fan than nothing. And try to make sure with your fingers that you do everything you have to do not well enough to pass, but in a way which makes you feel your life in your fingers in every movement you make. If you haven't got to the stage of taking out molars without breaking the roots, try taking a walnut out of its shell and its skin quickly without a break. It is a different dexterity but, I imagine, equally difficult.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surgs. Rear-Admirals P. T. Nicholls, C.B., M.R.C.S. Eng., and J. S. Dudding, C.B., O.B.E., M.R.C.S. Eng., have been appointed Hon. Physicians to the King.

Surg. Lt.-Comdr. E. T. S. Rudd to *Pembroke* for R.N.B., and to *Pegasus*.

Surg. Lt. M. Cay to *Dundee* (on recommg.).

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. W. H. Butcher to *Victory* for R.N.B.

Surg. Lt.-Comdr. C. Mason to *Victory* for R.N. Hospital, Haslar.

Surg. Lt. A. S. Pearson to be Surg. Lt.-Comdr.

Surg. Lt. E. C. Johnson to *Pembroke* for Chatham Hospital, and M. G. Stratford to *Royal Sovereign*.

Surg. Lt. (D.) H. P. Buchanan to *Pembroke* for R.N.B.

The following appointments as Admiralty Surgeons and Agents have been approved to date Oct. 1st, 1935: Mr. H. M. Clarke, 45, London-road, Reading; Mr. T. D. Gillies, Lynbridge House, Tavistock; Mr. H. L. Pearson, Granville House, The Spa, Gloucester; and Mr. A. M. Bayne, 76, Wimborne-road, Bournemouth.

ARMY MEDICAL SERVICES

The appointments announced under this heading in THE LANCET of August 24th (p. 457) took effect on Oct. 6th.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. A. M. Pollard, D.S.O., retires on ret. pay.

Maj. D. C. G. Ballingall, M.C., to be Lt.-Col.

MILITIA

Maj. A. Picken, O.B.E., M.C., resigns his commn. and retains the rank of Maj.

TERRITORIAL ARMY

Maj. W. Leslie, M.C., T.D., to be Lt.-Col.

Superannumary for service with the O.T.C.—Lt. E. Shipman to be Capt. Gordon Nuttall Bailey (late Cadet,

Uppingham Sch. Contgt., Jun. Div., O.T.C.), to be Lt. for duty with the Med. Unit, Univ. of Lond. Contgt., Sen. Div., O.T.C.

TERRITORIAL ARMY RESERVE OF OFFICERS

Lt.-Col. and Bt. Col. J. V. Bates, M.C., relinquishes his commn. and retains his rank, with permission to wear the prescribed uniform.

Capt. E. A. Downes, from T.A. Res. of Off. (Gen. List, Yeo.), to be Capt.

ROYAL AIR FORCE

Flying Offr. G. H. Morley is promoted to the rank of Flight Lt.

Flight Lt. (Quartermaster) F. W. Goodread is promoted to the rank of Squadron Leader.

Flight Lts. L. Freeman to No. 35 (B) Squadron, Bircham Newton; J. Kemp to No. 207 (B) Squadron, Bircham Newton; G. W. Paton to No. 3 (F) Squadron, Kenley.

Flying Offrs. C. A. Lewis to No. 29 (F) Squadron, North Weald; G. H. Morley to No. 12 (B) Squadron, Andover; J. W. Patrick to No. 12 (B) Squadron, Andover; W. G. S. Roberts to No. 33 (B) Squadron, Upper Heyford.

Dental branch.—Group Capt. C. Leslie Colbran, O.B.E., is placed on the retired list.

A new clause has been inserted into King's Regulations and Air Council Instructions to provide that an officer on half-pay who is likely to return to full pay may, with prior Air Ministry approval, be admitted to a Service hospital if suffering from a disability not attributable to the conditions of Air Force service. Other officers on half-pay may, with similar prior approval, be admitted to a Service hospital provided that the accommodation is not required for patients with a better title to admission. Retired officers who are not re-employed cannot as a rule be admitted to a Service hospital.

COLONIAL MEDICAL SERVICE

The following have been appointed Medical Officers, West Africa: Dr. A. G. W. Branch, Dr. E. J. Bury, Dr. H. C. Foster, Dr. A. F. Fowler, Dr. J. S. McGregor, Dr. K. O'Toole, Dr. J. D. Reid, and Dr. V. T. Thorne. Dr. D. A. P. Hopkin and Dr. R. M. B. Lewis, appointed Medical Officers, Malaya; Dr. A. C. Pilkington, Medical Officer, Zanzibar; Dr. D. A. Smith, Medical Officer, Hong-Kong; and Dr. J. B. Henderson, Assistant Medical Officer, Falkland Islands. Dr. B. F. Home becomes Medical Superintendent, Mental Hospital, Singapore; Dr. A. G. H. Smart, Senior Medical Officer, St. Vincent; Dr. M. V. Boucaud, Medical Officer, Grade I., Colonial Hospital, Port of Spain, Trinidad; and Dr. L. M. Ram, Assistant Medical Officer, British Honduras.

INDIAN MEDICAL SERVICE

The undermentioned officers have vacated appointments in India:—

A.D.H. and P.: Lt.-Col. R. Davidson, R.A.M.C.

A.D.M.S.: Col. E. W. C. Bradfield, C.I.E., O.B.E.; I.M.S., Col. H. C. Winckworth (late R.A.M.C.), Brit. Serv., Col. H. E. Stanger-Leathes, I.M.S.

D.A.D.P.: Major A. Mearns, R.A.M.C.

D.A.D.H.: Major T. O. Thompson, R.A.M.C.

The undermentioned appointments have been made in India:—

A.D.H. and P.—Maj. T. O. Thompson, R.A.M.C.

A.D.M.S.—Bt. Col. W. H. Hamilton, C.I.E., C.B.E., D.S.O., I.M.S.

D.A.D.P.: Capt. T. B. Pahlajani, I.M.S.

D.A.D.H.: Maj. G. K. Fulton, R.A.M.C.

Lt.-Col. (Bt. Col.) W. H. Hamilton, C.I.E., C.B.E., D.S.O., to be Col.

Majs. to be Lt.-Cols.: H. C. Tait, M.B.E., W. J. Webster, M.C., J. C. Chukerbuti, and A. M. Ghosh.

Cpts. to be Majs. (provl.): R. L. Frost, J. C. Drummond, D. M. Fraser, and J. F. Shepherd.

Lt. (on prob.) C. W. A. Searle is seconded while holding an appointment at Addenbrooke's Hospital, Cambridge.

Indian Medical Department: Cpts. (Sen. Asst. Surgs.) to be Majs. (Sen. Asst. Surgs.): T. J. Gibson and J. H. S. Hutton.

OBITUARY

ERNEST MUIRHEAD LITTLE, F.R.C.S. Eng.

WE regret to announce the death of Mr. Muirhead Little at his home in London on Oct. 2nd in his eighty-second year.

Ernest Muirhead Little was born in July, 1854, at Ealing, the fourth son of William John Little, M.D., F.R.C.P., who founded the Royal Orthopædic Hospital, gave his name to spastic paraplegia, and wrote a treatise on club-foot and analogous distortions. It was perhaps natural for that one of his sons who adopted medicine as a career to specialise in the same direction. Moreover, Dr. Little suffered from some shortening of the tendo Achillis for which Louis Stromeyer had treated him by division of the tendon, and Stromeyer was a welcome visitor at the Littles' home in Grosvenor-square; so there was much talk in the house about orthopædic surgery.

Muirhead Little was educated at Westminster School, which continued throughout life to claim

his affection and to which later he sent his own sons. He went on from there to University College. On leaving college he went into business, but not for long; finding it uncongenial he made his escape to St. George's Hospital. His studies were interrupted during the Turco-Servian war of 1876, when he joined the ambulance sent out by the National Aid Society, and he did not qualify until 1880. From 1882-86 he was dispensary surgeon at the Dreadnought Hospital, and in the latter year, having taken the

[Photograph by Elliott & Fry]

MR. MUIRHEAD LITTLE

F.R.C.S. Eng., he was elected surgical registrar to the National Orthopædic Hospital and in due course gained a position on the honorary staff. Orthopædic surgery was then a very minor specialty; treatment was mostly instrumental and surgical interference confined to subcutaneous sections. Operations at the hospital were performed by the whole staff on one morning in the week, the out-patient waiting hall being temporarily converted into a theatre. Conditions at the Royal Orthopædic Hospital were similar, except that it was the house surgeon's sitting-room which was commandeered on Monday afternoons by two porters bearing a massive wooden operating table. No wonder that the King's Fund intervened and in 1905 secured the joining up of the Royal and the National Hospitals, to be united later to the City Hospital. Little was himself not at first in favour of this amalgamation, which was however to afford him the opportunity of practising modern surgery in a hospital of 446 beds instead of the 50 then at his disposal. After the charter had been granted, a small room on the ground floor facing Bolsover-street was converted into a permanent operating theatre.

But Little was then over fifty and lack of opportunity had already handicapped him in acquiring new surgical technique; so that when the present hospital in Great Portland-street was opened in 1909 it was almost too late for him to take full advantage of its facilities. Ten years later he had reached the retiring age.

There were other positions in which Muirhead Little's gifts were not subject to artificial restriction. In 1895 he was appointed surgeon to the Royal Surgical Aid Society in succession to Herbert Allingham, son of William Allingham, the society's first surgeon. Little held that office for 39 years; on one occasion he saw no less than one hundred patients in the day and was very proud of it. Every year for 24 years he described the work of the Society in response to the Lord Mayor's invitation at the Mansion House meeting. During the war he was in surgical charge of Queen Mary's Auxiliary Hospital at Roehampton where disabled officers and men were fitted with artificial limbs. Many stumps were unsuitable for fitting and required re-amputation, and he brought an immense experience to the aid of these difficult cases. At this time he published a book on artificial limbs and amputation stumps which is the standard book of reference on the subject. Later he worked for the Ministry of Pensions. In 1913 he was vice-president of the orthopædic section at the International Congress of Medicine in London. Contending interests were rendering the committee's task of selecting an opener for the first discussion difficult, when the suggestion that Little should open on Little's disease settled at once both opener and subject. In the same year he was elected the first president of the subsection of orthopædic surgery of the Royal Society of Medicine and remained in that office until 1919. He was also chosen to preside over the newly formed British Orthopædic Association.

In a wider circle Little came to exercise increasing influence. His judgment was sound, his knowledge of the literature of orthopædic surgery was encyclopædic, his writings were compounded of erudition and scholarship. Many of them were published in our own columns, the subjects including scoliosis, spina bifida, coxa vara, Pott's disease, and absence of the patella. That he might have been a historian is evident from the admirable History of the British Medical Association, 1832-1932, first published as a series of articles in the British Medical Journal and then reprinted in book form with portraits and pictures. He had no enemies and excited no professional jealousy. Mr. Laming Evans writes: "Muirhead Little was of striking appearance and his good looks remained with him throughout his old age. He might easily have been mistaken for a bishop or a judge. Of abstemious habits, he went out to dine only for the sake of congenial companionship. His entertainments in Seymour-street were simple and kindly, enjoyed by his guests for the brilliance of his conversation. He was not keen on games, but enjoyed a country walk. He was a frequent attendee at the Casual Club, and more than once read a paper there. To all with whom he came in contact he endeared himself; house surgeons respected him, nurses obeyed him with alacrity, and he was adored by his patients, of whose case histories he was tolerant almost to indulgence. His religious views were broadminded and sincere, and he carried them into his daily life."

Mr. Muirhead Little married in 1890 Mary, only daughter of John Burgess Knight, and is survived by his widow, one daughter, and three sons.

DR. GEORGE BRYCE, who died at Torquay on Oct. 3rd in his 75th year, was living in retirement after a life spent in general practice. Born in the village of Whitburn, near Bathgate, Linlithgowshire, he received his medical training at St. Mungo's College, Glasgow, where he won many medals and qualified in 1895. He then settled in the Lozells district of Birmingham where he developed a large general practice, publishing a number of interesting cases in the Midland Medical Journal. In 1911 he took the M.D. degree for practitioners at Durham University. But this was only one side of Dr. Bryce's activities. He joined the Royal Geographical Society and was an ardent supporter of the Peary Arctic Club, publishing in 1911 a historical survey entitled "The Siege and Conquest of the North Pole." After retirement he was able to indulge his love of travel, and in 1931 went up the Amazon with Mr. James L. Palmer, editor of the Western Morning News in search of rare butterflies and plants. To the herbarium at Kew Gardens he presented specimens

of rare Arctic plants that he had gathered in Spitzbergen, and he made an extensive study of the insect life of Labrador.

Of his three children two qualified in medicine at Birmingham: his son is carrying on the Lozells practice, a daughter is in partnership at Torquay.

WILLIAM CARR HUMPHREYS, M.R.C.S. Eng., was a well-known figure in Swansea, where he died after a fall which broke a leg. He was in his 79th year, and had lived for 50 years in a house at the corner of Cradock-street and Northampton-place. Born in Oswestry, he was educated at Bromsgrove School and Queen's College, Birmingham, where he qualified in 1881. His connexion with Swansea began with residence at the General Hospital to which later he became out-patient medical officer. He was before everything the family doctor, always efficient and always at hand when wanted. Throughout life he retained his love of the open air and was often to be seen bathing from the sands or working in his allotment on Town Hill. His personal expenses being small—he never married—he endeared himself by countless acts of generosity. His rounds he did in a horse-drawn brougham.

CORRESPONDENCE

AN APPEAL TO MEDICAL BENEVOLENCE

To the Editor of THE LANCET

SIR,—A part of the work of the Royal Medical Benevolent Fund which has won the very special sympathy and support of many of your readers in previous years is the distribution of Christmas gifts. Undoubtedly it is due to the fact that this particular appeal touches the heart and kindly feelings of all as it comes at the season of good fellowship. Once again I venture to make my appeal in your columns for donations, either large or small, in order that the Fund may continue the distribution of 30s. each to all beneficiaries.

I cannot but feel impressed when I read the many letters of thanks which are received from the recipients after Christmas Day. Clearly these letters are written from homes where no luxuries exist, and where the greatest economy has to be studied; often from cheap lodgings or single bed-sitting-rooms where lonely ones rejoice in the fact that they have not been forgotten. But all the letters contain expressions of gratitude and thanks to those who have made the gift possible.

I do not wish to stress unduly the needs and difficulties of our less fortunate medical brethren or of those who were once near and dear to them. But I do desire to assure your readers of the great work the Benevolent Fund is doing in bringing some happiness and comfort into the lives of many. This kindly work is being carried on thanks to the generous support which the committee has received, but it can only be continued and increased if we still receive the support and sympathy of our professional colleagues.

Donations should be sent, and cheques made payable, to the hon. treasurer, Royal Medical Benevolent Fund, 11, Chandos-street, London, W.1, who will gratefully acknowledge them.

I am, Sir, yours faithfully,

THOS. BARLOW,

Sept. 12th. President of the Royal Medical Benevolent Fund.

IMMUNISATION AGAINST SCARLET FEVER

To the Editor of THE LANCET

SIR,—Your leading article last week under this heading omits mention of one of the chief difficulties of the problem. I refer to the fact that scarlet fever is not really a disease at all. The term was applied to a group of symptoms before their cause was understood. Now we know that "the rash" of scarlet fever is caused by the exotoxin of certain hæmolytic streptococci in persons devoid of antitoxin. The hæmolytic streptococci will cause tonsillitis without the rash in persons possessing the antitoxin. This tonsillitis is just as likely to be followed by complications in those who do not get the rash as in those who do, and is highly infectious. By immunisation an entirely false sense of security is obtained. The immunised no longer get the rash but they are just as liable to get recurrent tonsillitis. However, tonsillitis without a rash is not "officially" scarlet fever, and no particular attention is paid to it or isolation of the infected person insisted upon.

The following example illustrates this point:

In a certain children's hospital, where the nurses had been immunised against scarlet fever for some years, an epidemic of tonsillitis occurred in a ward. Some seven children were involved, two of whom got a scarlatina-form rash. The cause of the trouble was found to be the staff nurse who had a "sore-throat." The organism obtained from the throats of all the children was identical—i.e., a hæmolytic streptococcus which produced a fairly strong exotoxin on culture. The two children with the rash were said to have "scarlet fever"; the others and the nurse "tonsillitis." The children with the rash were sent to a fever hospital; the others were not.

On it being suggested to the matron that the staff nurse had scarlet fever "in her throat" the former became angry and pointed out with some vigour that all her nurses had been immunised against scarlet fever and were known to be immune, adding that if every nurse with a "hospital throat" was to be treated as if she had scarlet fever she (the matron) would not have any nurses left.

Space does not permit me here to enlarge any further on this curiously anomalous position, but it is

clear that before immunisation of school-children is generally recommended a more scientific understanding of the problem by the profession is needed.

I am, Sir, yours faithfully,

Dublin, Oct. 7th.

MEDICAL ASSESSORS

To the Editor of THE LANCET

SIR,—Your important leading article upon this subject makes plain the fact that the laws of England empower judges of the High Court to call medical assessors if they think fit. The question in the last paragraph of your article is, for the time being, a sufficient commentary upon the rarity with which they take advantage of the power placed in their hands. Your article touches the fringe only of most complicated legal, medical, social, and religious questions. Turning to one side only, eminent legal authorities fully realise that the legal position with regard to responsibility for crime urgently needs a complete overhauling. England at present is doing nothing to prevent the increase of mentally deficient members of the population. Take one aspect. There can be no doubt that mental deficients are constantly being sent to prison, some more than once. No counsel will put forward a plea of insanity on a trifling charge involving six months' imprisonment. In these cases the plea of insanity not having been raised, the presence of a medical assessor would be useless. If the mentally deficient prisoner be found guilty, or not guilty, the person is subsequently liberated to continue a career of crime and legitimately, or frequently illegitimately, increases the number of mentally deficients in this country.

Let it be supposed that a judge accepts the presence of a medical assessor, would he be able to examine the prisoner, consider the past record and family history, before giving his opinion? Answers to these questions are essential in order to form that opinion. I have recently seen the record of a mentally deficient who has been twice imprisoned, but is now fortunately in an institution where, let us hope for the sake of the community, he will remain.

I am, Sir, yours faithfully,

Harley-street, W., Oct. 7th. G. LENTHAL CHEATLE.

ASCARIS INFECTION

To the Editor of THE LANCET

SIR,—In THE LANCET of August 10th last there is an annotation on ascaris infection; in this a passage from our editorial of last June on the same subject is described as a suggestion for the "... deliberate fouling of the usual drink of hundreds of millions. ..." Such a strong expression is scarcely excusable on any grounds, and we feel sure it must have escaped your personal notice; it could only emanate from someone who has been out of personal contact with tropical conditions for many years and who has not kept himself au fait with recent advances in tropical sanitation.

Our experiences in numerous discussions with those who have installed or are proposing to install these latrines has been that the question of the proximity to wells and of the possibility of fouling these is always most carefully considered as a matter of course. In an article which was not a complete discussion on bore-hole latrines in all their aspects but one written to draw the attention of sanitarians in India, and in Assam in particular, to a form of latrine that has been thoroughly "tried out" and been

found of great value in other tropical countries, it was not considered necessary to reiterate fundamental principles of sanitation.

In a comprehensive scientific discussion on bore-hole latrines, the question of well pollution, about which there is already a certain amount of experimental data available, would have to be given full consideration.

I am, Sir, yours faithfully,

L. EVERARD NAÏER,
Editor, Indian Medical Gazette.

School of Tropical Medicine, Calcutta, Sept. 19th.

* * Bore-hole latrines are designed to carry infective material into the ground water, and if this polluted water should reach drinking-water wells the fouling of the drinking water is not accidental but the result of deliberate action. This was the sense in which the words "deliberate fouling" were used in our annotation. The question is whether the migration of pathogenic bacteria does actually take place from latrine to well. C. H. Yeager, one of the pioneers of this type of latrine, working at Singapore for the Rockefeller Foundation, showed that the colon bacillus was carried in the subsoil water 70 feet in 19 days irrespective of the direction of its flow, and American observers have traced still more extensive migration. But in his latest publication which has just reached us Yeager remarks that bore-hole latrines are "very much safer than we believed before the bacteriologic work during the past two years was completed." If this experimental work, which has not yet been published, should justify the proximity of latrines to wells, believed from actual experience, a free from risk, the bore-hole latrine would be gladly accepted by sanitarians the world over.—Ed.

"A CURIOUS EPIDEMIC OF SORE-THROAT"

To the Editor of THE LANCET

SIR,—The account in your issue of Sept. 28th (p. 740) of an epidemic of sore-throat at a Northants village reminds me of a rather similar outbreak which occurred at the Midland Counties Asylum at Knowle, near Birmingham, in April, 1908, reported in your columns at the time (THE LANCET, 1908, ii., 1814). In this outbreak a nurse first complained of pharyngitis and tonsillitis which rapidly spread to other nurses on the female side, then to the male nurses and to a number of the male inmates. The throat infection was at first thought to be Klebs-Löffler, but diphtheria bacilli could not be found in the swabs although diphtheroid bacilli were present and there was plentiful growth of both streptococci and staphylococci. When this epidemic abated a similar but more severe one occurred in my practice at a private proprietary school where the boys fell down like ninepins, the whole class going sick one by one, all with similar symptoms and local signs. One boy died of cardiac failure fourteen days after onset of symptoms. His was the only throat with Klebs-Löffler bacilli; all the others showed Hofmann's diplococci and streptococci, but no diphtheria bacilli, except in one case in which the local throat signs were slight. During the epidemic the masters and servants in the school had slight pharyngitis with no constitutional disturbance. At the same time as this occurrence an epidemic of diphtheria prevailed in the neighbouring parishes.

I am, Sir, yours faithfully,

Rowington, Warwick, Oct. 5th.

J. O. HOLLOCK.

ORIGIN OF BOILS

To the Editor of THE LANCET

SIR,—It would be interesting if dermatologists would give opinions in your columns regarding the aetiology of boils on the neck. Do they consider that the failure on the part of most hairdressers to sterilise their clippers, scissors, and combs may be a contributory cause? If so, do they consider that the immersion of instruments in surgical spirit would be of value? Opinions on the sterilisation of brushes would also be useful. The neck clipper, when dissected, reveals an astonishing collection of hair, and I believe that organisms may easily be conveyed from one customer to slight abrasions on the neck of another. In view of the frequency of the condition it seems desirable that the matter should be ventilated. Infection, sometimes severe, of the eyebrows certainly follows plucking, and I think furuncle of the nostrils often arises from the same cause. It may therefore be that occasional epilation by blunt clippers allows access to organisms already present, and the idea that the clipper itself conveys infection may be quite wrong. It seems, however, well worth while to discuss the matter in the hope that hairdressers will, if necessary, coöperate in any measures that the dermatologists consider desirable.

I am, Sir, yours faithfully,

Beeston, Notts, Oct. 7th.

L. P. LOCKHART.

EVIPAN SODIUM WITH PREMEDICATION

To the Editor of THE LANCET

SIR,—The value of Evipan Sodium as a general anæsthetic was so ably put forward by Mr. Dickson Wright in your issue of May 4th that I was persuaded to give this barbiturate an extended trial. The following points, arising out of its use in 125 cases during the last few months, may be of interest to some of your readers.

Having to treat a large number of cases of abortion sent into St. Giles Hospital, we decided to use evipan anæsthesia for those whose symptoms demanded surgical intervention. At first it was found that the patients came into the operating theatre apprehensive and excited, and several of them appeared to be very resistant to the drug. Preliminary medication was indicated, and cautiously adopted, and it was found that if it was given at least *one hour* before operation, and if the evipan sodium solution was injected into the vein slowly and by stages, then a uniform and uneventful anæsthesia was obtained. As a routine dose (of course subject to modification to suit special needs) omnopon gr. 1/3 with hyoscine hydrobromide gr. 1/150 has been given to our last 120 cases 1-1½ hours before operation. We have strictly adhered to this time interval between premedication and the exhibition of the barbiturate, and to the following technique when injecting the latter. The uniform success of the practice has inspired our confidence.

After premedication the action of the evipan given intravenously is so consistent that we have become accustomed to regard its dosage as almost uniform in its effect upon the patients. An ampoule of the substance contains one gramme (grs. 15) and this must be completely dissolved in the 10 c.cm. of sterile distilled water from an ampoule which is also provided by the makers. From 2.0 to 2.5 c.cm. of the solution is *slowly* injected into a suitable vein in front of the forearm (we take about fifteen seconds to do this) and the patient is carefully observed. No attempt is made to get her to count herself out,

but a few words of encouragement are spoken to enlist the aid of "suggestion," so valuable in the induction stage of any general anæsthetic.

This initial dose of say 2.5 c.cm. in fifteen seconds is almost always sufficient to produce unconsciousness. The action of the drug can be clearly seen in the rather sudden relaxation of all muscles. As soon as the initial loss of consciousness occurs the injection is stopped, and it will usually be noticed that there is a transient cessation of respiration. It seems proper to await passively the natural return of the normal respiratory rhythm before giving any further injection. In our series this has always occurred after twenty or thirty seconds.

The return of a normal respiratory rhythm is the indication for the injection of a second 2.0-2.5 c.cm. of the solution, which is given as slowly as the first. A careful watch is kept on the patient during this second phase, and again the respiratory rhythm is seen to fade away. This time a longer interval is allowed to elapse and the return of good respiratory movement awaited passively. A period of about sixty seconds for this second interval has proved quite satisfactory before the final dose of another 2.0-2.5 c.cm. is given, and this is injected as slowly as before. Thus about two minutes are allowed in which to inject 7.0-7.5 c.cm. of the solution.

After the final dose the patient is in a deep sleep; yet we have found that the course of the anæsthesia runs more smoothly if she is left undisturbed for at least another minute. Nothing should be allowed to disturb her during the induction stage, unless an attempt to hasten the return of respiratory movements by pressure on the chest-wall is indicated; nor should too hurried a start be made with the operation. We have found that, as with an inhalation anæsthesia, a smooth passage into unconsciousness, and a little time allowed for the body to become accustomed to the altered conditions, ensures very much more satisfactory results.

In this series of cases which have received premedication the action of the evipan has been so uniform that we have found that 2.0-2.5 c.cm. (grs. 3½) may be confidently expected to induce sleep, and that our total dose for a general anæsthesia lasting some fifteen or twenty minutes has averaged 7.5 c.cm. (grs. 10). It has been found easier to control the dosage when the solution is injected in three stages and in approximately equal proportions, as has been described.

Observations have been made upon the blood pressure of some of our patients during the course of this anæsthetic. A Baumann's sphygmomanometer was used in place of the usual tourniquet, and it was seen that there was a transient fall of 15-20 mm. Hg in the initial stages of the induction, rarely more. The pulse-rate rises slightly, as expected with the small fall of blood pressure, and then remains very steady, and a "good pulse" throughout the operation is usual. We have learned to pay most attention to the patient's respiration, and have been guided by this both for the rate of injecting the solution, the amount to be given, and the duration of the interval between each part of the dose. It has not been found necessary to disturb the patient by inserting an airway.

If it is desired to counter too large a dose, or if for any reason it should become necessary to hasten the recovery of consciousness at any stage, Coramine has been used. The contents of two ampoules (3 c.cm.) are injected intravenously. Almost immediately the patient's respiratory movements

quicken and become deeper; then there are vague movements of the limbs and head, the pulse quickens, and more colour is diffused into the face. It is stated that 10 c.cm. of coramine may be given, but we have never required more than 5 c.cm. After the initial stimulation passes off, the patient usually continues to sleep on quietly, but can be roused by any vigorous action of an attendant.

If left alone after operation a patient usually sleeps on peacefully for a couple of hours; the exact time seems to depend upon her individual need for sleep. She awakes refreshed, without any feelings of nausea, and has none of the distressing symptoms so often associated with recovery from an inhalation anaesthetic.

The conclusions reached so far are: (1) that the barbiturate derivative sodium evipan is a rapid and pleasant general anaesthetic for surgical operations of short duration, and that it is notably free from any unpleasant after-effects; (2) that in a series of 120

cases premedication has greatly facilitated the action of this drug; (3) that the premedication we have used, without any alarming or unexpected symptoms in any case, has no marked contra-indications; (4) that the clue to its successful use is a very careful observation of the patient's respiration; (5) that in order to guard against any real depression of the respiratory centre a sufficiently long interval of time must be allowed to elapse between the administration of the preliminary medication and the administration of the sodium evipan. It has been found that *one hour* is the minimum interval and one and a half hours the optimum time that should be allowed to elapse after using the narcotic mentioned.

This series of cases is too small to justify final opinions, but thus far the method has given entirely satisfactory results.

I am, Sir, yours faithfully,

R. W. NICHOL,
Assistant Medical Officer, St. Giles
Hospital, Camberwell.

Oct. 8th.

PUBLIC HEALTH

THE NEW HOUSING ACT

At a meeting of the Royal Sanitary Institute last Tuesday Lord BALFOUR of BURLEIGH presided, and Dr. JAMES FENTON read a paper on the Housing Act, 1935.

The housing problem, Dr. Fenton said, was one for which no Government had so far found a satisfactory solution, and many would think that further legislation would soon be needed, although the new Act brought many improvements. Its most outstanding feature was perhaps the establishment of a national standard of overcrowding. A house was now overcrowded when it was necessary for any two persons over ten years of age and of opposite sex (excluding spouses) to sleep in one room; or alternatively when it was inhabited by more than the permitted number of persons as set out in a schedule of the Act. The permitted number was calculated from two tables based on the floor area and on the number of rooms. A child under one year did not count, and a child between one and ten was half a unit. A room with floor area of less than 50 square feet was excluded. Dr. Fenton described the application of this standard to his own district of North Kensington, where previously a standard of 400 cubic feet of air for adults and 200 cubic feet for a child under ten had been applied to old areas, but 450 cubic feet had been required in improvement areas for every person, regardless of age. This was higher than the standard anywhere else in the country, but not as high as that of the new Act. In a typical street of an improvement area in North Kensington there were 145 houses of the terrace type, each with eight good-sized rooms and a small slip-room. These were let out to 3, 5, or more working-class families. In 1932 these houses had held 625 families (2386 people), an average of just over 16 people per house. Over 80 per cent. of the rooms had been used both for living and sleeping, and on the lower of the two cubic feet standards only 21 of the families had been overcrowded. In 6 families the overcrowding could have been remedied by adjusting the sleeping arrangements, and the displacement of only 19 persons would have abated it in the remainder. When the standard of 450 cubic feet per person has been applied in 1934 it had been found that 103 families, consisting of 643 persons, were overcrowded. When

the standard of the new Act was introduced, after rigid application of the old standard had eliminated overcrowding, it was found that 68 families, consisting of 368 persons, were living in conditions now regarded as overcrowded. Nevertheless the standard of the new Act was not too high for a built-up area. It was apt to be severe on houses with large rooms, but would permit a theoretical density of 330 persons per acre in the street he had in mind. The provision that a baby did not count gave the family a year's notice before they had to move into larger premises. A survey of North Kensington had shown that there were some 2000 or 3000 families living in overcrowded conditions, out of a total of 20,134, although the bye-law standards had been rigidly enforced.

There had been no serious obstacles to the completion of the survey. The first survey might be described as a "door step" survey, for the enumerator only had to ascertain the number of rooms and need not enter the house, though he usually did so. He probably knew the number of rooms in the house before he knocked at the door, and one or two questions and the use of his eyes would show him whether that particular house was different from similar ones already familiar to him. He then had to obtain from some intelligent occupant the number of families and individuals and their ages and distribution in the rooms. He could visit approximately 50 houses in the day, with perhaps 15 failures to obtain the required information. In Kensington it had been found that one man could get the necessary information in 250 houses in one week with a population of 2500. One clerk could cope with the forms brought in by six enumerators. The second survey was a much more detailed affair as it required information of the size of the rooms. It was quite unsafe to assume that all houses in a terrace had rooms of the same size. One worker would not be able to cover more than 50 houses a week, and sometimes five or six visits had to be paid. Again one clerk could deal with the material brought in by six survey assistants.

The duty of local authorities to enforce the overcrowding provisions fell into two parts: prevention and abatement of overcrowding arising after and existing on the appointed day. The provisions of the Act relating to the first part were definite and not difficult to enforce. The landlord must take

reasonable steps, when letting, to ensure that the number would not be excessive, and must notify the local authority within seven days if he subsequently became aware of overcrowding. The occupier could then be served with a notice requiring abatement without offering alternative accommodation. If the occupier or a member of his family persisted in the offence, the local authority could apply to a magistrate for vacant possession, expenses being recovered from the landlord. This was an innovation. The problem of existing overcrowding was a little more difficult. An occupier was not guilty of an offence unless he was offered suitable alternative accommodation: adequate housing, near his work, with security of tenure, at a rate within his means.

Mr. J. S. WHEELER (Housing Inspector, Kensington) reminded his audience that the rooms vacated by one family might bring relief to a smaller family. The officers of bodies concerned in Kensington were notified several weeks in advance of rooms which would become vacant and had frequently been able to approach owners and urge them to let rooms to families known to be living under unsatisfactory conditions. New accommodation of 74 flats had enabled the authorities to abate overcrowding in 144 families of 1001 persons. An important innovation in the new Act was the introduction of redevelopment procedure. An area suitable for redevelopment was one containing at least 50 working-class houses of which one-third were overcrowded, unfit for human habitation, not repairable at reasonable cost, or congested in arrangement. Redevelopment in a large city like London would, Mr. Wheeler thought, prove extremely difficult. The cost would be great and the number rehoused might not justify it. Moreover, the Exchequer grant was less generous than that of the 1930 Act. The new Act provided that houses which were only dangerous to health because of bad arrangement were paid for at market value instead of site value if they stood in a clearance area. If the local authority made a clearance order requiring the owner to demolish, they must themselves purchase and demolish such houses. A mixed house—i.e., one only partly used for habitation—might be included in a clearance order if any part used for dwelling was unfit by reason of disrepair or sanitary defects. Very few houses would prove to be dangerous solely by reason of bad arrangement; they generally had sanitary or repair defects. The increased cost to local authorities arising out of the amendment which prescribed market-value compensation for such buildings, was not therefore likely to be great. If the Minister was satisfied that a house had been well maintained, although rightly included in a clearance or compulsory purchase order, he might direct the local authority to pay compensation over and above site value. An amendment of special interest to health officers was that the local authority must give an objecting owner their reasons for declaring his house unfit at least 14 days before the public inquiry. In Kensington the evidence of the medical officer and sanitary inspectors was prepared well in advance, and anybody could see it. Cross-examination would be shortened and the case strengthened by putting in advance copies of the evidence. Another new provision allowed a local authority to enforce closure of any part of a house, whether let separately or not and even if not occupied. Any unfit underground room could be closed.

In answer to questions, Dr. FENTON said that in

the Kensington survey no differentiation had been made between working-class houses and any other type; the survey had been directed to congestion irrespective of social distinctions. Neither landlord nor tenant had been notified of the survey, but less than a dozen objections had been encountered. The information given by a responsible head of a family was reliable in the great majority of cases. The service of notices would take as much time and money as house-to-house visitation, and was far less satisfactory as it always required verification by visit in the end. The standard of overcrowding was the potential accommodation available to any one family, even if in fact they all chose to sleep in one room.

School Medicine in the Future

MANY school medical officers were moved by the jubilee of their service to review its progress and achievements, and the widening of its scope; some of them gave their views about what is still to be hoped for. No one has made such incisive comment or advocated such radical alteration as Dr. Henry Herd (Manchester), who has expressed in clear and outspoken language thoughts that have been floating in many minds. The present statistical table prescribed by the Board of Education does not, he thinks, give a true picture of the health of school-children and it encourages too intense a concentration on the discovery of defects and diseases. School doctors, in common with others, have learnt that "there is a time to speak and a time to keep silence in the case of enlarged tonsils," but the policy might be extended to other conditions such as certain varieties of heart disease. His main criticisms of the present system are these: (1) lack of opportunity for continuous study of the individual child; (2) the static character of the present investigation. All we are getting now is merely three cross-sections of the child's condition at four-year intervals; of what goes on between the routine examinations nothing is known. Dr. Herd insists on the need for periodical supervision at shorter intervals; better still would be a continuous record from infancy. As an example he cites the record of nutrition and he approves the scheme of the London County Council whereby a continuous record of height and weight is made from measurements taken twice a year. A record of this kind is facilitated by a card designed by Dr. E. D. Irvine (Blackburn), starting from the infant welfare period and going on through school life, which he hopes may be of value to medical officers of juvenile instruction centres, factory medical officers, and even to panel practitioners. Dr. Herd points out that the emotional reactions of children to their surroundings are fundamental even for their physical growth and development. The school service should study the psychological problems which at present are relegated to child guidance clinics; this would necessitate child psychiatry being part of the equipment of every school medical officer.

Dr. Herd's second point is that it is not enough to adjudge a child healthy because it shows no abnormality when at rest under examination. There should be study, by careful observation of the child's work and play, of how the whole organism is functioning. As it is children are now often brought forward as special cases by observant teachers. Tests of physiological fitness, as Dr. H. E. Magee has pointed out (*THE LANCET*, 1935, i., 268), have still to be put in practice, for scientific evidence of functional derangement before organic change sets

in would make prevention possible in the true sense. Two of the tests mentioned by Dr. Herd are the subject of report during 1934: the use of the dynamometer by Dr. A. T. Powell (Walthamstow), and the estimation of hæmoglobin by Dr. S. F. Reynolds (Manchester); while the respiratory test has been studied in previous years by Dr. J. V. A. Simpson (Torquay) and Dr. J. G. Woolham (Manchester).

Dr. Herd's final point is that instruction in hygiene should be given by the school doctor. It is, he says, altogether anomalous that the officer who has to deal with defects arising from faulty hygiene should take no part in teaching how to prevent them. Here he is in agreement with the London County Council scheme for medical care of those over 14 years of age, which lays down that the medical officer inspecting the adolescents should be himself the lecturer in hygiene.

A Doubtful Case of Typhus Fever

The last weekly return contained the notification of a case of typhus fever from the Port of London. Dr. C. F. White, medical officer of health for the port, informs us there is an element of doubt about the diagnosis. The circumstances were these:

A male Chinese, aged 41, embarked as a steerage passenger at Hong-Kong on August 14th. He was last ashore at Penang on August 23rd. On Sept. 4th he had a slight febrile attack but his temperature returned to normal the next day. On Sept. 11th he had a shivering attack, complained of headache and backache and took to his bed. The ship's surgeon found his temperature to be 103° F. On Sept. 14th he developed a macular eruption, profuse on the abdomen, chest, and back, but sparse on the arms and legs. This rash became petechial and was confluent in the groins and axillæ. The patient was dull and stupid and the ship's surgeon diagnosed typhus fever.

On arrival in the Port of London on Sept. 18th the boarding medical officer found the man with a temperature of 103° F., pulse 130, respirations 30. His face was somewhat bloated, the conjunctivæ injected, the tongue dry and brown, and there were sordes on the lips. He was dull and apathetic, and it was difficult to attract his attention. There was a coarse macular and petechial eruption as described. There was bronchial congestion at the base of the right lung. No pediculi corporis or capitis were found but pediculi pubis were in evidence.

The patient and his wife were removed in the ambulance launch to the port sanitary hospital, being deloused before admission to the cubicle ward. The Chinese crew were also taken ashore and deloused; meanwhile their quarters and the ship's hospital were fumigated with sulphur dioxide. The passengers and white crew were medically examined and all were found well. In hospital the rash faded and the temperature fell to normal on the twelfth day from the onset. There was no enlargement of the spleen, slight albuminuria and obstinate constipation.

Samples of blood were sent to two bacteriologists, both of whom reported the Weil-Felix reaction negative, but the Widal strongly positive (1 in 640 for *B. typhosus*).

Although bacteriologically the case was considered to be typhoid, clinically the eruption, the history, and the general appearance of the patient were characteristic of typhus fever.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 28TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2289; diphtheria, 1128; enteric fever, 68; acute pneumonia (primary or influenzal), 520; puerperal fever, 37; puerperal pyrexia, 85; cerebro-spinal fever, 10; acute poliomyelitis, 20; encephalitis lethargica, 6; dysentery, 34; ophthalmia neona-

torum, 86. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the infectious hospitals of the London County Council on Oct. 4th was 2743, which included: Scarlet fever, 926; diphtheria, 1028; measles, 23; whooping-cough, 321; puerperal fever, 18 mothers (plus 12 babies); encephalitis lethargica, 269; poliomyelitis, 16. At St. Margaret's Hospital there were 17 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox or enteric fever, 7 (0) from measles, 1 (0) from scarlet fever, 18 (6) from whooping-cough, 20 (6) from diphtheria, 69 (15) from diarrhoea and enteritis under two years, and 18 (2) from influenza. The figures in parentheses are those for London itself.

Deaths from diarrhoea and enteritis were distributed over 27 great towns, the highest being Liverpool 12, Leeds 7, Sunderland and Birmingham each 5, no other great town more than 2.

The number of stillbirths notified during the week was 272 (corresponding to a rate of 43 per 1000 total births), including 45 in London.

MEDICAL NEWS

University of Cambridge

At recent examinations the following candidates were successful:—

D.M.R.E.

Part II.—Hans Jungmann, D. W. Lindsay, D. F. MacDonald, J. W. McLaren, Alfred Pollitt, N. C. Sinha, I. G. Williams, and C. W. B. Woodham.

University of London

Three lectures on the comparative histophysiology of the vertebrate nephron will be given at University College, Gower-street, W.C., by Dr. Pol Gerard, professor of histology in the University of Brussels, on Oct. 22nd, 24th, and 25th at 5.30 p.m. Admission without ticket.

University of Liverpool

At recent examinations J. B. Mackie, H. E. C. Sutton, and Patricia I. Unsworth were successful in obtaining Part II. of the diploma in public health.

British College of Obstetricians and Gynaecologists

The following have been awarded the diploma of the College (D.C.O.G.) after examination:—

P. N. Bardhan, Wilfrid Bradley, J. O. F. Davies, E. G. Frewer, S. M. Green, B. P. Harris, A. M. Hunter, W. M. Martin, N. H. Merchant, R. A. Nash, P. W. Rice, S. H. Swift, H. T. Tate, Doribai Valiram, J. A. Walker, J. W. Walker, and B. E. Warm.

Medico-Legal Society

The first meeting of the session will be held at Manson House, 26, Portland-place, London, W., at 8.30 p.m. on Thursday, Oct. 24th, when Mr. C. A. Mitchell, D.Sc., will deliver a presidential address on forensic medicine in relation to medicine. Manson House, the headquarters of the Royal Society of Tropical Medicine and Hygiene, will be the Medico-Legal Society's meeting-place for the future. The annual dinner is to be at the Holborn Restaurant on Friday, Dec. 13th. The hon. secretaries are Mr. Ernest Goddard (3, South-square, Gray's Inn, W.C.1) and Dr. W. G. Barnard.

Industrial Welfare Society

At 5.30 p.m. on Tuesday next, at 14, Hobart-place, London, S.W., Dr. S. W. Fisher, H.M. medical inspector of mines, will give an address on the medical aspects of a miner's life to the advisory medical committee of this society. Dr. D. A. Coles, who is retiring from the chairmanship of the committee, is being entertained at dinner at the Goring Hotel, Ebury-street, S.W., at 7.45 p.m. on the same day.

Post-graduate Course on Tuberculosis

From Nov. 4th to 9th a post-graduate course will be given, under the auspices of the Joint Tuberculosis Council, by the medical and surgical staff of the Brompton Hospital for Consumption and Diseases of the Chest, London. There will be two lectures each morning and each afternoon (except Saturday), and the meetings will be held at the hospital. Further particulars may be had from Dr. William Brand, 8, Christchurch-place, Epsom, Surrey.

HOSPITAL DINNERS

Charing Cross Hospital

The annual dinner of past and present students of Charing Cross Hospital medical school was held at the Café Royal on Oct. 5th. In the absence of Dr. A. W. Oxford, who was prevented by ill-health from taking the chair, Mr. Norman C. Lake presided, and pointed out the difficulties of understudying one who was doctor of medicine, doctor of divinity, Greek scholar, antiquarian, and philatelist. A message of sympathy was sent to Dr. Oxford. In proposing the toast of the hospital and the medical school Mr. Lake spoke of the hope, once entertained, of turning the old nurses' home into a block of private wards. The nurses were now safely housed in their new quarters at Haverstock Hill, but the architectural disadvantages of the old home could not be overcome without rebuilding. The Charing Cross tradition, linked with memories of Huxley and Livingstone, did not depend upon bricks and mortar, and he felt that the hospital would be subserving the interests of science best if it were rebuilt. This was the centenary year of the medical school, which was now more prosperous than it had ever been. Mr. C. J. Marshall, presuming on a friendship which had, on Mr. Lake's admission, "withstood the co-authorship of a text-book," gave some happy reminiscences of the chairman, and Mr. Eric A. Crook, the dean, spoke of the proposal to bring back the teaching of anatomy and physiology to the medical school. He also referred to the great loss to the hospital during the past year in the deaths of Dr. W. J. Adie and Dr. W. Howard Jones. Dr. Gordon M. Holmes proposed the toast of the visitors, coupling it with the names of Prof. D. M. Blair and Mr. R. T. D. Stoneham. Mr. Herbert J. Collings baffled the company agreeably with conjuring tricks, and recounted the story of the consultant who undertook to examine a patient for fifty guineas. "Do!" said the patient, "and if you find them you can have half."

St. Thomas's Hospital

The old students' dinner was held at the Dorchester Hotel on Oct. 4th, when Sir Cuthbert Wallace presided over a gathering of nearly two hundred. The chairman having remarked that they were there to learn something about the hospital and the school, Sir Arthur Stanley said that as far as the hospital was concerned things were going on well. The reconstruction of the outpatient department was now complete, and "something that will do for a medical school" (even if not up to the dean's expectation) was going up at a cost of about £70,000, none of which would fall on hospital funds. Six of the eight wards had been remodelled and the amenities of College House had been improved, especially by the addition of a veranda. Lady Riddell's gift had made it possible to rebuild the nurses' home, complete with swimming bath. That released accommodation in the paying block, a matter in which St. Thomas's had led the way and should not be dropping behind. Sir Arthur ended with an appeal to his hearers not to let people think St. Thomas's was rich, but to take every opportunity of denying such an impression, for the hospital needed £20,000-£30,000 a year to keep it going, and £100,000 now for capital expenditure. Prof. L. S. Dudgeon, who replied for the school, joined with Sir Arthur Stanley in congratulating the chairman on having obtained the highest post in the surgical profession. He besought him during his term of office to make some effort at co-operation between the College and the medical schools. He spoke with regret of the retirement of Mr. Nitch with whom he had entered the school. He recorded sundry honours to St. Thomas's men, including the translation of Prof. LeGros Clark to the chair of anatomy at Oxford, and mentioned the addition to the dissecting-room of an X ray department for anatomical study of the live body. He set out the good athletic record of the year and concluded with a tribute to the scheme for co-operation with the medical schools of St. Bart's and Guy's. Prof. T. B. Johnstone, dean of Guy's, who responded to the toast of The Guests, said he entered gladly into the entente cordiale, the aim being to give students of the three schools something they had not had before, but he reminded his hearers that after the separation of St. Thomas's

and Guy's in 1825 there had been a united hospitals dining club of which he gave some entertaining details. Dr. A. E. Russell proposed the health of The Chairman, to which Sir Cuthbert Wallace replied by remarking: "If you get out of St. Thomas's Hospital what I have got of joy and happiness you will be very lucky." The formal proceedings closed at the early hour of 10 to allow conversation and social intercourse.

King's College Hospital

The annual dinner of past and present students of King's College Hospital was held on Oct. 5th, at the May Fair Hotel, with Sir Charlton Briscoe in the chair. Dr. G. F. Still, consulting physician and professor emeritus for diseases of children, was presented by the chairman with a book containing the names of subscribers to the fund which was collected for his portrait exhibited in this year's Academy. Thanks to the generosity of the artist, Mr. Gerald Kelly, the proceeds for the fund are to be devoted to an endowment of a cot in the children's ward. Sir Charlton Briscoe spoke of the great loss sustained in the resignation of the Duke of Connaught from the presidency of the hospital, and expressed his pleasure that the Duke of York had consented to succeed him as president. Dr. J. A. Drake, the dean, announced that the medical school was more flourishing than it had ever been, and reported the opening of a new biochemical laboratory. He made a special reference to Dr. Willoughby Lyle's book, "King's and Some King's Men," which contains, he said, a wealth of information about everything and everybody who has had anything to do with King's. Dr. Still returned thanks for the gift book presented to him, and Dr. R. H. Lee told entertaining stories of the time when the chairman was a student and house surgeon.

The Duke of York will preside for the first time as president of King's College Hospital at the festival dinner to be held at Claridge's on Thursday, Nov. 14th. He will announce the programme for the further development of the hospital.

Memorial to Miss Davies-Colley

A memorial is being raised to the late Eleanor Davies-Colley, M.D., F.R.C.S., and donations may be sent to the honorary treasurer, Miss Chadburn, at 16, Harley-street, W.1. The sum raised will be used mainly for the benefit of the South London Hospital.

Chadwick Public Lectures

The autumn programme of the Chadwick Trust includes a lecture by Dr. Killick Millard on the Vaccination Question To-day, which will be given on Friday, Nov. 1st, at Manson House, 26, Portland-place, London. On Tuesday, Nov. 19th, at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C., Prof. R. C. McLean will speak on the bacteriology of the atmosphere. Both lectures will be at 5.30 P.M. Further particulars of the programme may be had from the secretary, Mrs. Aubrey Richardson, at the offices of the Trust, 204, Abbey House, S.W.1.

Hampstead General and North-West London Hospital

The sixth winter session of post-graduate lectures at this hospital will open on Wednesday, Oct. 16th, at 3 P.M., when Mr. Herbert Naylor, physical director of the Y.M.C.A., will speak on health and exercise. Other lecturers will be: Dr. Saxby Willis, thoracic pain (Oct. 23rd); Mr. D. H. Patey, traction in the treatment of fractures and dislocations (Oct. 30th); Dr. H. V. Morlock, diagnosis and treatment of intrathoracic new growths (Nov. 6th); Mr. H. Lawson Whale, fads and fancies in laryngology (Nov. 13th); Dr. H. Courtney Gage, radiology of the genito-urinary tract (Nov. 20th); Dr. Adolphe Abrahams, insomnia and other disturbances of sleep (Nov. 27th); Mr. Peter Finigan, aims and methods of modern dentistry (Dec. 4th); Mr. S. A. Boyd, surgery of the biliary passages (Dec. 11th); and Mr. Arthur Gray, common difficulties in gynaecological diagnosis (Dec. 18th). All the lectures except the first will be at 4 P.M.

British Postgraduate Medical School

Dr. W. B. Coley, of New York, will give an address on post-graduate teaching in America at the school (Ducane-road, Shepherd's Bush, W.) at 12.15 P.M. to-day, Friday, Oct. 11th.

Lectures on Psychology for Nursing Sisters

The matron of Guy's Hospital has made arrangements for a course of 8 lectures on elementary psychology and methods of teaching, to be given to those members of her nursing staff, notably "sisters and other responsible persons," whose duties include the training of probationers. The course is being given by Miss Alice M. Jackson, B.A.

London Hospital Medical College

Chronic pancreatitis has been selected as the subject for the Hutchinson triennial prize which will be awarded in 1938. The conditions of the prize may be obtained from the dean of the college.

British Institute of Philosophy

The presidential address of this institute will be given by Sir Herbert Samuel, M.P., at University College, Gower-street, London, W.C., on Tuesday, Oct. 15th, at 8.15 P.M. He will speak on New Science and Old Philosophy. Application for tickets should be made to the director of studies at University Hall, 14, Gordon-square, W.C.1.

Maternity Home for Southampton

On Oct. 3rd the Minister of Health, Sir Kingsley Wood, laid the foundation-stone of a maternity hom at the Borough Hospital, Southampton.

Sussex Medical and Dental Golfing Society

The sixth autumn meeting of the society was held on Oct. 6th, on the links of the Brighton and Hove golf club. J. Scott Page won the Captain's trophy (3 up) and Gregg and Glover and Wallace and McAleenan tied with a score of 4 up in foursomes against bogey.

Surgical Instrument Manufacturers' Association

The annual dinner of this association will take place at the Holborn Restaurant, London, W.C. (entrance in Newton-street), on Friday, Oct. 25th, at 7 P.M. The principal guest will be Prof. G. Grey Turner.

British Orthopaedic Association

The annual meeting of this association will be held in Manchester on Oct. 25th and 26th under the presidency of Mr. Harry Platt. The main subject for discussion will be fractures of the os calcis. Mr. B. L. McFarland and Mr. W. J. Eastwood will speak on its economic consequences; Dr. E. E. Myers, of Boston, U.S.A., will report the results of attempted reduction in a series of recent fractures; and Mr. R. Ollerenshaw and Mr. A. H. Todd will deal with the treatment of old fractures. A number of short papers will also be given.

A Vocational Filter

An exhibition of scientific aids to management, arranged by the department of industrial co-operation of the British Association, is on view at British Industries House, Marble Arch, London. It is substantially the same as that assembled for the Association's meeting in September, and its aim is to call attention to the new phenomenon of the science of management. One of the exhibits, shown in this country for the first time, is a French device, known as a series of "grilles," for helping to determine occupational fitness. The grilles consist of a number of celluloid charts. All the occupations recognised by the French National Statistical Office have been analysed in regard to the physical qualities they demand, and given an index number which appears in the master chart. Apart from the master chart, there are 32 grilles, each of which relates to a specific physical or physiological characteristic in which the person to be tested may have been found defective. When all the grilles relating to characteristics in which the subject is defective are superposed on the master chart, the index numbers of the occupations for which he has no physical disability are still visible. The grilles may thus be regarded as a medical filter through which people may be passed to ensure that, at any rate, they are not put into vocations for which it can be shown at the outset they are gravely handicapped.

Royal Academy of Medicine in Ireland

Dr. R. A. Stoney has been elected president of the Royal Academy of Medicine for 1935-36, with Dr. T. C. P. Kirkpatrick as general secretary and Dr. William Doolin secretary for foreign correspondence. The general council consists of Dr. E. T. Freeman, Dr. Gibbon FitzGibbon, Dr. W. G. Harvey, Mr. A. A. McConnell, Dr. W. R. O'Farrell, and Dr. J. P. Shanley. The sectional presidents are: medicine, Dr. V. M. Synge; surgery, Mr. Seton Pringle; obstetrics, Dr. J. F. Cunningham; pathology, Dr. W. R. O'Farrell; anatomy and physiology, Dr. J. M. O'Connor; State medicine, Dr. J. A. Harbison; laryngology and otology, Mr. S. H. Law.

German Pharmacological Society

The twelfth meeting of this society will be held in Munich from Oct. 20th to 23rd under the presidency of Prof. Sigurd Janssen of Freiburg. Prof. E. B. Verney, of Cambridge, will open the first discussion, on the renal excretion of mammals and its physiological regulation. Other subjects to be debated are the relationship between chemical constitution and pharmacological action, anaesthesia and basal narcosis, and circulatory stimulants. Prof. Behrens (Dorotheenstr. 28, Berlin, N.W.7) is secretary of the congress.

Medical Diary**SOCIETIES**

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Oct. 14th.

United Services. 4.30 P.M. Air Commodore A. V. J. Richardson: Efficiency of Personnel in the Services (presidential address).

TUESDAY.

General Meeting of Fellows. 5.30 P.M.

Pathology. 8.15 for 8.30 P.M. J. C. Mottram: Some Tumours in Fowls by Radiation, I. Muende: Pigment Studies. S. L. Baker: Paget's Disease of the Skin. R. Hare: Classification of Hemolytic streptococci by the Group Precipitin Reaction.

J. Ross: Three Cases of Splenomegaly.

THURSDAY.

Dermatology. 5 P.M. (Cases at 4 P.M.) Dr. H. Haldin-Davis: 1. Papillomata occurring in Creosote Worker. Dr. Bertha Lewis (introduced by Dr. H. C. Semon): 2. Spoon Nails Associated with Cheilitis and Microcytic Anemia. Dr. G. Bamber: 3. Epidermolysis Bullosa. Dr. J. E. M. Wigley: 4. Case for Diagnosis. ? Artefact. ? Radio-dermatitis. Dr. R. Klaber: 5. Folliculitis Decalvans et Atrophicans with Lichen Spinulosus. Dr. Louis Forman: 6. Parapsoriasis. Dr. H. C. Semon: 7. Papillomatosis. 8. Lupus Erythematosus treated with Antileprol.

Neurology. 8.30 P.M. Dr. F. L. Golla: The Nervous System and the Organic Whole (presidential address).

FRIDAY.

Radiology. 7 P.M. Dr. C. G. Teall: Whither Radiology? (presidential address).

Obstetrics and Gynaecology. 8 P.M. Dr. J. W. Burns, Mr. C. M. Marshall, and Mr. D. W. Roy: The Treatment of Breech Presentations with Special Reference to Cases of Extended Legs and Arms. Mr. Aleck Bourne, Mr. Eardley Holland, and Mr. G. F. Gibberd will also speak.

HUNTERIAN SOCIETY.

MONDAY, Oct. 14th.—8.30 P.M. (Simpson's Restaurant, Bird-in-Hand-court, 76, Cheapside), Dr. W. B. Brander: The Challenge of the Sick (presidential address).

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, Manson House, 26, Portland-place, W.

THURSDAY, Oct. 17th.—8.15 P.M., Sir Arthur Bagshawe: Presidential Address.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

FRIDAY, Oct. 18th.—4 P.M., Sir Henry Dale, F.R.S.: Some Epochs in Medical Research (Harveian oration).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 14th, to SATURDAY, Oct. 19th.—NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W. All-day course in cardiology.

METROPOLITAN HOSPITAL, Kingsland-road, E. All-day course in medicine, surgery.

MEDICAL SOCIETY OF LONDON. Wed., 4 P.M., Mr. Malcolm

Gynaecology.—NATIONAL

Hampstead-road, N.W. Tues., 8.30 P.M., Mr. A. S. Parkes, F.R.S.: Ovary. Thurs., 8.30 P.M., Dr. H. Gardiner-Hill: Thyroid.—ROYAL WESTMINSTER OPH-

THALMIC HOSPITAL, Broad-street, W.C. Tues., 5 P.M., Mr. C. L. Gimblett: Some Points in Medical Ophthalm-

ology. Wed., 5 P.M., Mr. G. G. Penman: Demonstration of Fundi of Medical Interest.—INFANTS HOSPITAL, Vincent-square, S.W. Mon., Wed., and Fri., at 8 P.M., course in anatomy and physiology.—CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C. Sat. and Sun., course in obstetrics. (Open only to members of the Fellowship.)

LONDON HOSPITAL, E.
WEDNESDAY, Oct. 16th.—10 A.M., Mr. Keizer: Epithelial Odontomata and Treatment. 11 A.M., Dr. A. Maitland-Jones: Tuberculosis in Infancy and Childhood. Noon, Dr. M. H. Jupe: X-ray Diagnosis of Pregnancy. 1.30 P.M., Dr. G. Riddoch: Demonstrations of Neurological Cases. 2.30 P.M., Dr. William Evans: Angina Pectoris, its Problems and Treatment. 3.30 P.M., Mr. C. Donald: Present Position of Thyroid Surgery. 4.30 P.M., Mr. Victor Dix: Retention of Urine.

THURSDAY, 10 A.M., Mr. C. B. Goulden: Significance of Ciliary Infection. 11 A.M., Dr. Donald Hunter: Science and Empiricism in Therapeutics. 12 noon, Dr. A. Burrows: X-ray and Radium Treatment of Diseases of the Skin. 1 P.M., Mr. Eardley Holland: The Clinical Applications of Recent Work on the Female Sex-hormones. 2 P.M., Dr. John Parkinson: Cardiac Enlargement. 3 P.M., Dr. Horace Evans: Cases of Renal Disease. 4.15 P.M., Prof. Bulloch, F.R.S.: Medical Periodical Literature (Schorstein lecture).

FRIDAY, 10 A.M., Mr. R. Milne: The Technique of Splints, Crutches, &c. 11 A.M., Mr. N. Patterson: Some Remarks on Bronchoscopy and Oesophagoscopy. 12 noon, Mr. W. S. Perrin: Modern Treatment of Piles. 2 P.M., Mr. R. Howard: Surgical Demonstrations. 3 P.M., Dr. O. Leyton: High Carbohydrate Diets in Diabetes. 4.15 P.M., Dr. G. E. Vilvandre: Some Results of X-ray Treatment.

SATURDAY, 10 A.M., Dr. E. H. Tallerman: Feeding and Management of Young Infants. 11 A.M., Mr. A. M. A. Moore: The Fracture Problem. 12 Noon, Sir James Walton: The Surgery of Jaundice. (Open only to former students of the hospital.)

KING'S COLLEGE HOSPITAL, Denmark Hill, S.E.
THURSDAY, Oct. 17th.—9 P.M., Dr. R. R. Trail: Sanatorium Treatment of Tuberculosis.

NATIONAL HOSPITAL, Queen-square, W.C.
MONDAY, Oct. 14th.—3.30 P.M., Dr. Kinnier Wilson: Aphasia, Apraxia (2).
TUESDAY.—3.30 P.M., Dr. Purdon Martin: The Cranial Nerves (2).
WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.
THURSDAY.—3.30 P.M., Dr. Riddoch: The Sensory System (2).
FRIDAY.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (2).
 Out-patient clinic daily at 2 P.M.

ST. PAUL'S HOSPITAL, Endell-street, W.C.
WEDNESDAY, Oct. 16th.—4.30 P.M., Mr. H. P. Winsbury-White: The Etiology of Urinary Calculus.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Oct. 17th.—2 P.M., Dr. Reginald Lightwood: Reticuloendotheliosis. 3 P.M., Dr. A. Signy: Specific Immunisations. (II.). Out-patient clinics daily at 10 A.M., and ward visits (except Wednesday) at 2 P.M.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.6.
MONDAY, Oct. 14th.—10 A.M., medical and surgical wards, skin clinic. 2 P.M., gynaecological and surgical wards, eye and gynaecological clinics. 4.15 P.M., Mr. Green-Armstrong: Mistakes in Diagnosis.
TUESDAY.—10 A.M., medical wards and dental clinic. 11 A.M., surgical wards. 2 P.M., throat clinic. 4.15 P.M., Dr. Konstam: Heart Block.
WEDNESDAY.—10 A.M., children's wards and clinic, medical wards. 2 P.M., eye clinic. 4.15 P.M., Mr. Harvey Jackson: Minor Surgery of the Rectum.
THURSDAY.—10 A.M., neurological and gynaecological clinics. Noon, fracture clinic. 2 P.M., eye and genitourinary clinics. 4 P.M., venereal diseases. Noon, Lecture on Treatment. 2 P.M., throat clinic. 4.15 P.M., Dr. Hugh Gordon: Acne.
SATURDAY.—10 A.M., surgical and children's clinics, medical wards. The lectures at 4.15 P.M. are open to all medical practitioners without fee. Operations and medical and surgical clinics daily at 2 P.M.

UNIVERSITY OF LONDON.
TUESDAY, Oct. 15th.—3 P.M. (University College Hospital medical school), Prof. Charles Singer: Some Important Contributions to Medical Science emanating from University College Hospital.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.
TUESDAY, Oct. 15th.—5 P.M., Dr. H. D. Haldin-Davis: Acne and Rosacea.
WEDNESDAY.—5 P.M., Dr. I. Muende: Histopathology of Common Skin Diseases.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.
THURSDAY, Oct. 17th.—8 P.M., Dr. L. A. Rowden: Looking Backward and Looking Forward (pre-idential address).

ROYAL INSTITUTE OF PUBLIC HEALTH.
MONDAY, Oct. 14th, TUESDAY and WEDNESDAY.—4 P.M. Institute of Hygiene, 25, Portland-place, W. Dr. P. Armand-Delille: Problems of Nutrition and Growth. (In English.)

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, W.C.
WEDNESDAY, Oct. 16th.—4.30 P.M., Prof. R. A. Fisher, F.R.S.: Eugenics and National Health.

GENERAL INFIRMARY, Leeds.
TUESDAY, Oct. 15th.—3.30 P.M., Mr. Moir: Demonstration of Surgical Cases.

PUBLIC DISPENSARY, Leeds.
WEDNESDAY, Oct. 16th.—4 P.M., Dr. H. H. Moll: Pneumonia.

ANCOATS HOSPITAL, Manchester.
THURSDAY, Oct. 17th.—4.15 P.M., Dr. R. Ellis: Medical Treatment of Urinary Infections.

ROYAL INFIRMARY, Manchester.
TUESDAY, Oct. 15th.—4.15 P.M., Mr. A. Graham Bryce: Abscess of the Lung.
FRIDAY.—4.15 P.M., Dr. J. Wharton: Demonstration of Ophthalmic Cases.

Appointments

FULD, HEINZ, M.B. Berlin, M.D. Heidelberg, L.R.C.P. Edin., has been appointed Senior Resident Medical Officer at the Birkenhead Municipal Hospital.

HALL, G. S., M.B. Birm., M.R.C.P. Lond., First Assistant in the Neurological Department at the General Hospital, Birmingham.

STRÖM-OLSEN, ROlf, M.D. Wales, D.P.M., Hon. Psychiatrist to the East Ham Memorial Hospital.

Births, Marriages, and Deaths

BIRTHS

BAIFOUR.—On Sept. 27th, at Cowes, I.W., to Ana Balfour, M.B. Edin. (née Van Hoesen), wife of George Macdonald Balfour, M.B. Edin.—a daughter.

BURGESS.—On Oct. 2nd, at Clifton, Bristol, the wife of Norman Burgess, M.D. Camb., of a daughter.

EDWARDS.—On Oct. 4th, in a London nursing-home, the wife of Harold C. Edwards, F.R.C.S., of a son.

MANDOW.—On Sept. 26th, at Sheerness, Kent, the wife of Dr. G. A. Mandow, of a daughter.

NELSON.—On Oct. 4th, at Bentinck-street, W., the wife of Dr. Alan Nelson, of a son.

PRIDIE.—On Sept. 30th, the wife of Kenneth H. Pridie, F.R.C.S. Eng., Clifton, Bristol, of a daughter.

SHARPEY-SCHAFER.—On Sept. 28th, the wife of E. P. Sharpey-Schafer, M.R.C.P. Lond., of a daughter.

MARRIAGES

ALLEN-DUNNE.—On Oct. 3rd, 1935, at St. Wilfrid's Church, Cantley, near Doncaster, by the Archdeacon of Doncaster, the Venerable F. G. Sandford, M.A., assisted by the Rev. W. M. Tatham, M.A., Vicar of Cantley, and the Rev. G. Needham, B.A., Rector of Braithwell, Charles Henry Belton Allen, the Royal Ulster Rifles, only son of Major H. G. Allen, O.B.E., and Mrs. Allen, of Sidecup, Kent, to Katharine Elizabeth Mary Dunne, M.R.C.S., L.R.C.P., only daughter of Dr. A. B. Dunne, J.P., and Mrs. Dunne, of Cantley Lodge, Cantley, near Doncaster.

CHURCHER-NAYLOR.—On Sept. 27th, at Trinity-road Chapel, Upper Tooting, Dr. James C. Churcher, of Haifa, Palestine, to Gladys Louise Naylor, daughter of Mr. Alfred Naylor, Wandsworth Common.

JONES-MCCREA.—On Sept. 28th, at St. Mary Magdalene, St. Leonards-on-Sea, Ivor J. Jones, M.B. Lond., D.P.H., to Margaret, daughter of Dr. B. H. McCrea, of Bargoed, Glamorgan-shire.

O'NEARA-RIDLEY.—On Oct. 3rd, at St. James's Church, Spanish-place, London, D. J. Patrick O'Neara, F.R.C.S. Edin., of Bury St. Edmunds, to Joan Cowell, younger daughter of Mr. A. Paul Ridley, Felixstowe.

RATCLIFFE-GREENALL.—On Oct. 3rd, at St. Jude's Church, Mapperley, Nottingham, Tom Arundel Ratcliffe, B.A., M.B., B.Chir., to Norah, only child of Mr. and Mrs. A. N. Greenall, of Nottingham.

TRIPP-THOMAS.—On Sept. 28th, at St. Paul's Church, Sketty, Swansea, Reginald Christopher Howard Tripp, M.R.C.S. Eng., Flying Officer, R.A.F., to Barbara, elder daughter of Frank Thomas, M.B. Camb., of Swansea.

1885-1935. GOLDEN WEDDING

LEECH-BOWYER.—On Oct. 10th, 1885, at St. Chrysostom's Church, Victoria Park, Manchester, by the Rev. T. N. Carter, M.A., Priestley Leech, M.D. Lond., F.R.C.S. Eng., eldest son of the late John Leech, J.P., to Emmie Melson, only daughter of the late Frances Yates Bowyer, of Manchester, King Cross, Halifax.

DEATHS

FISHER.—On Sept. 28th, at Cleethorpes, W. H. Fisher, O.B.E., T.D., M.D. Camb., Lt.-Col., R.A.M.C. T. (ret.), aged 69.

HUMPHREYS.—On Oct. 1st, at Swansea, William Carr Humphreys, M.R.C.S. Eng., aged 79.

LITTLE.—On Oct. 2nd, at A-bley-gardens, S.W., Ernest Muirhead Little, F.R.C.S. Eng., aged 81.

PAIK.—On Oct. 6th, at Folkestone, Charles Henry Leet Paik, M.B., F.R.C.S. Edin., Lt.-Col., Indian Medical Service (ret.).

SMELLY.—On Sept. 28th, at Hadleigh, Suffolk, Charles Edward Smelly, M.A., M.D. Camb., M.R.C.S. Eng., late of Hertford, aged 81.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts

A RADIUM TELL-TALE

THE intention of Westminster Hospital, at its Annexe in Hampstead, to resume the use of a bomb containing four grammes, or double the quantity of radium now employed, has again raised the question of the safety of the operators, who must be daily in close proximity to this powerful source of radiation. While the new radium bomb will be continually at work for the whole twenty-four hours, no one operator will be concerned for more than a spell of eight hours in each day. During this time he will be required to spend an average of two minutes each hour in adjusting the bomb to the patient; and he may thus himself receive an exposure of sixteen minutes in all in the course of his duties. It is the accumulation of these daily small exposures, continuing for a period of months or even years, which has to be observed and controlled.

Besides the routine precautions always taken—namely, blood examination, regulation of rest and vacations, and, of course, the screening of the radium with heavy metals—it is the intention of the radium department of Westminster Hospital to make a systematic use of a new "tell-tale" which can be carried in the pocket of the operator, and which will reveal, on examination at the end of the day, how much effective exposure the operator has received.

Devised by the physicist of Westminster Hospital Annexe, it is based on principles investigated by research workers in Sweden. When going on duty the operator will take from a cabinet a small tube of elektron metal about two inches long, and in so doing will operate a simple clocking-in apparatus which indicates the time at which he takes possession of his tell-tale; at the end of the period for which he is on duty he will replace the tube and at the same time clock out. Inside the tube is a thin rod of elektron, which is supported on highly insulated amber buttons and charged to about 400 volts. The radiation from the radium which the operator encounters in the course of his work will cause this charge to leak off and the amount that leaks will measure the dose received. It will thus be possible to keep from day to day a complete record of the incidental exposures received by each operator, and to ascertain whether these are within the safe limits or not. If there is an increase in the case of any individual, immediate steps can be taken both to check his methods and to prevent ill-effects; if there is a general increase, then further safeguards must be incorporated in the apparatus. All the tests so far made are said to indicate that the protection now afforded is fully satisfactory.

A MEDICAL SCULPTOR.—A bust of Mr. Tielman Roos, the appeal court judge who as Minister of Justice did so much to reconcile old party divisions in South Africa, was unveiled by General Smuts at Bloemfontein on Sept. 10th. The sculptor was Dr. Joseph M. Coplans, a captain in the South African Medical Corps, who holds a qualification both in medicine and dentistry, and was at one time a student of St. George's Hospital, London.

Vacancies

BACTERIÆMIA AND ORAL SEPSIS
WITH SPECIAL REFERENCE TO THE
ÆTIOLOGY OF SUBACUTE ENDOCARDITIS

By C. C. OKELL, M.C., M.B. Camb., F.R.C.P. Lond.
PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LONDON
AND BACTERIOLOGIST, UNIVERSITY COLLEGE HOSPITAL; AND

S. D. ELLIOTT, M.B. Lond.

DEMONSTRATOR OF BACTERIOLOGY, UNIVERSITY COLLEGE
HOSPITAL MEDICAL SCHOOL

The following investigation owes its origin to certain observations made by T. Lewis and R. T. Grant on the relationship of congenital bicuspid aortic valves to subacute bacterial endocarditis. In an important paper¹ on this subject they bring forward evidence to show (1) that in an unselected series of 31 cases of subacute bacterial endocarditis 26 per cent. presented a congenitally bicuspid condition of the aortic valves and (2) that among those reaching adult life and possessing bicuspid aortic valves, 23 per cent. at least die of active endocarditis. From these data they develop the following almost unchallengeable argument:—

"The entry of organisms into the blood stream cannot be regarded as determining the disease, though it is a necessary link in the chain of events. The determining cause is the defective valve which in some way traps and holds the organisms once they have entered. From the standpoint of pathology the importance of the bicuspid valve group is that it indicates the frequency with which innocuous invasions occur amongst the general population. As infective endocarditis is responsible for death in but a very small percentage of adults generally, and as we can conclude that in these invasion of the blood stream is a common event,* we are forced to the further conclusion that such invasions are encountered in the great majority of instances without mishap. Relatively, the normally developed subject is highly immune to the disease, when he is compared with the bicuspid aortic subject, not because the organisms entering are of the wrong kind, not because they enter in insufficient numbers or possess insufficient virulence, not because appropriate general defences are called into play, but because his aortic valve presents no peculiar susceptibility to the lodgment and tenancy of organisms. The same line of reasoning minimises the importance of so-called primary foci of local suppuration in this group, as a cause of established endocarditic infection."

Our object has been to confirm by direct observation this hypothesis of what Lewis and Grant elsewhere in their paper refer to as an "almost physiological entry" of organisms into the blood stream of the average individual.

The Investigation

In searching for the ultimate source of the streptococci concerned in the production of subacute bacterial endocarditis, attention must inevitably be turned to the oral cavity. Practically all observers are agreed that the vast majority of endocarditis streptococci are of the salivary or *Streptococcus viridans* type. These abound in the mouth and its neighbourhood but are only found elsewhere in small numbers and under exceptional conditions; above all it is in conditions of oral sepsis such as pyorrhœa of the gums that this type of streptococcus is found in the greatest numbers.

BACTERIÆMIA FOLLOWING DENTAL EXTRACTIONS

Our first observations were made on the blood of patients undergoing extraction of teeth from both septic and clean mouths. It is admittedly not easy to classify the different varieties of oral sepsis. Gum infection and apical infection are rarely mutually exclusive conditions. We therefore divided the cases roughly into three groups, A, B, and C, shown in Table I.

The blood was examined for bacteria in 138 patients undergoing the operation of extraction of teeth. Ten cubic centimetres of blood were taken from the arm veins immediately before extraction, and another 10 c.cm. within five minutes after extraction. The blood was added to 1·2 c.cm. of 5 per cent. sodium citrate saline. Both samples of blood were usually taken while the patient was under the influence of a general anæsthetic—nitrous oxide, Evipan (intravenous), or ether.

TABLE I
Streptococcal Bacteriæmia Following Extraction of Teeth in 138 Cases

Case group.	Type.	Cases examined.	Result of blood culture after extraction.	Streptococcal colony counts. Average of aerobic and anaerobic cultures.				
				<1 c.c.	1-5 c.c.	6-10 c.c.	11-15 c.c.	>15 c.c.
A	Marked gum disease; multiple extraction.	40	30 ÷ 10 = (75% ÷)	5	17	2	2	4
B	Moderate gum disease; multiple extraction.	60	42 ÷ 18 = (70% ÷)	14	21	4	1	2
C	Without detectable gum disease; extraction of one or more teeth.	38	12 ÷ 26 = (34% ÷)	3	9	—	—	—

+ indicates that streptococci were present in the blood culture.
— indicates that no streptococci were present in the blood culture.
c.c. = per cubic centimetre.

Blood culture technique.—Each sample of citrated blood was distributed as follows. Two 1 c.cm. quantities were plated with 10 c.cm. agar in order to obtain a count of the viable organisms should the culture be positive. The remaining 8 c.cm. of blood was divided into two equal parts, each of which was added to 20 c.cm. of 0·1 per cent. sodium citrate broth. One blood-agar plate and one blood broth were then incubated aerobically at 37° C. for seven days; the remaining implants were incubated anaerobically at 37° C. for the same period. The aerobic cultures were inspected daily for the presence of bacterial growth; it was found that where the culture was positive, growth often first appeared on the third or fourth day of incubation.

It will be seen from Table I. that of 138 cases of dental extraction, 84 (60·9 per cent.) showed a transient streptococcal bacteriæmia after operation, and that in cases considered to be of a severe type of oral sepsis (Group A), the positive streptococcal cultures reached as high a figure as 75 per cent. In all cases where streptococci were recovered the organisms were of the non-hæmolytic type.

Table II. gives a comparison of the results obtained by aerobic and anaerobic methods of blood culture. In the majority of cases where the result was positive streptococci were recovered from the cultures grown under both conditions of cultivation, and in few instances were the organisms

* Meaning that it occurs in many adults.

TABLE II
COMPARISON BETWEEN AEROBIC AND ANAEROBIC METHODS OF BLOOD CULTURE.

Case group.	Type.	Cases examined.	Result of blood cultures after extraction.		Streptococcal colony count.									
					<1 c.c.		1-5 c.c.		6-10 c.c.		11-15 c.c.		>15 c.c.	
			Ae.	An.	Ae.	An.	Ae.	An.	Ae.	An.	Ae.	An.	Ae.	An.
A	Marked gum disease; multiple extraction.	40	27 + 13 - (67.5% +)	26 + 14 - (55% +)	6	5	13	9	5	5	3	1	—	6
B	Moderate gum disease; multiple extraction.	60	36 + 24 - (60% +)	31 + 29 - (51.7% +)	13	4	17	18	4	5	1	1	1	3
C	Without detectable gum disease; extraction of one or more teeth.	38	13 + 25 - (34% +)	10 + 28 - (26% +)	9	—	3	8	1	1	—	1	—	—

Ae. = aerobic.

An. = anaerobic.

c.c. = per cubic centimetre.

+ indicates that streptococci were present in the blood cultures, and — that no streptococci were present in the blood cultures.

found in the aerobic or anaerobic cultures only. None of the streptococci recovered were obligatory anaerobes.

In general, it was found that the occurrence and degree of a bacteraemia depended upon the severity of the gum disease and the amount of damage done at the operation. Of 10 cases where one tooth was extracted and where there was no noticeable gum disease, only one gave a positive streptococcal blood culture after operation; this was one of removal of an impacted wisdom tooth. In 6 cases where two carious teeth were removed from an otherwise normal mouth, 2 gave a positive streptococcal blood culture after operation, the number of colonies growing being less than 1 per c.cm. of blood.

In 10 cases where a positive culture was obtained directly after extraction, a third specimen of blood was taken at a period varying from ten minutes to eight hours after operation. After these intervals the blood was always found to be sterile. The bacteraemia following extraction is thus of very short duration.

Organisms other than streptococci found in the blood following extraction of teeth.—While in the majority of cases non-haemolytic streptococci were isolated in pure culture, in 6 of the 138 cases already described (in which the blood was cultured before and after extraction of teeth), diphtheroid bacilli were found in the blood taken immediately after operation. In 3 of these cases the diphtheroid organisms were in pure culture while in the remaining 3 they were present with streptococci. In no case were these organisms present in the aerobic and anaerobic cultures at the same time; in 5 cases they grew aerobically and in 1 case anaerobically. Two of these cases showed no gum affection. In 2 further cases included in the series of 138, staphylococci were found in the blood taken after extraction. These organisms were of the *albus* type; once they grew in pure culture, while in the remaining case they were mixed with streptococci. In both instances they grew only in the aerobic cultures.

The isolation of staphylococci and diphtheroids, both found so commonly on the surface of the skin, is possibly but improbably to be ascribed to contamination.

PIREXIA FOLLOWING EXTRACTION OF TEETH

In 20 of the cases where teeth were extracted from patients with pyorrhoea, the temperature was taken at half-hourly intervals over a period of twelve hours following operation. In 14 of these patients some degree of pyrexia was found to occur four to nine hours after operation; the temperature usually rose sharply to a level between 99° and 102° F. and remained at this height for two to four hours, after

which it fell abruptly to normal again. In 3 a third specimen of blood was taken during the pyrexial period, but in all it was found to be sterile although streptococci were found in the sample taken immediately after extraction of the teeth. In 3 of the cases where pyrexia was observed the blood culture immediately following extraction was negative, while in 3 where there was no rise in temperature a bacteraemia immediately followed operation. Three further cases showed neither a positive blood culture nor pyrexia following operation.

These observations cannot be said to show any clear relationship between post-operative bacteraemia and pyrexia. The time relationship, however, between the trauma, the bacteraemia, and the pyrexia was very similar to that observed by Barrington and Wright² in connexion with catheter fever, and possibly bears the same interpretation as that suggested by these observers—viz., that the pyrexia follows the bacteraemia at an interval similar to that which elapses between the injection of bacteria or protein into the circulation and the subsequent pyrexia (non-specific shock).

BACTERIEMIA IN RELATION TO DENTAL SEPSIS

The most unexpected of our findings was that in 12 cases streptococci were isolated from a specimen of blood taken before operation. Of these, 9 were amongst the 100 cases of pyorrhoea referred to in Table I. (Groups A and B), streptococci being found both before and after extraction of teeth. The remaining 3 cases were from an additional 10 cases of pyorrhoea in which only one examination of the blood was made, that being before extraction. Thus, among 110 cases of pyorrhoeal disease, 12 (10.9 per cent.) were found to have a streptococcal bacteraemia at the time of examination, irrespective of operative procedures. In 5 cases there was a definite increase in the colony-count of the specimen taken immediately after extraction of teeth, in 1 case there was a diminution in numbers, and in 3 cases less than one colony grew per c.cm. of blood, both before and after operation, so that no change in degree of the bacteraemia could be detected.

The blood of 2 of the patients was examined on two occasions, the tests being separated by an interval of a week. In both patients streptococci were found to be present in the blood on the second but not on the first occasion. In 3 of the 9 cases where streptococci were found in the blood both before and immediately after extraction, the blood

was examined again one to six hours after operation but was then always found to be sterile. It appears, then, that the inflammatory reaction following extraction closes down the field of absorption of organisms.

Organisms other than streptococci found in the blood before extraction of teeth.—In 6 of the 110 cases of pyorrhoeal disease mentioned above, staphylococci were isolated in pure culture from the blood before dental extraction. All six were of a severe type of gum disease. Two of the six staphylococci were hæmolytic for horse blood, one being of the *aureus* type.

THE STREPTOCOCCI

Type of streptococci found in the blood before and after extraction of teeth.—All the organisms classed as streptococci were of typical morphology, showing long or short chain formation. None of the organisms isolated showed the appearances characteristic of hæmolytic streptococci when grown on the surface of horse-blood agar. The positive streptococcal cultures consisted mainly of organisms, surface colonies of which caused some degree of green discoloration of blood pigment, although in a few instances they were mixed with streptococcal colonies which had no observable effect.

The fermentation reactions of 36 of the streptococcal strains isolated were tested with lactose, mannitol, and salicin:—

- 16 fermented lactose only (*salivarius* type of Holman).
- 9 " " and salicin (*mitis* type of Holman).
- 1. " salicin only.
- 10 " neither lactose, salicin, nor mannitol.

The fermentation reactions of a similar number of streptococci recovered from the blood of patients with subacute bacterial endocarditis were as follows:—

- 10 fermented lactose only.
- 9 " " and salicin.
- 7 " salicin only.
- 5 " lactose, mannitol, and salicin.
- 1 " mannitol and salicin.
- 4 " neither lactose, salicin, nor mannitol.

Serology of streptococci recovered from the blood before and after dental extraction.—A detailed study of the serology of streptococci from cases of subacute bacterial endocarditis and their relationship to mouth streptococci will be the subject of a subsequent communication by one of us (S. D. E.). For the present purpose it will suffice to state: (1) that serological matches for streptococci isolated from definite cases of endocarditis are frequently found among streptococci derived from the gums and blood of patients undergoing dental extraction; (2) that in patients where streptococci were found in the blood after, or both before and after, extraction of teeth, organisms of a similar serological nature could in many cases be recovered from the gums; (3) that more than one serological type of non-hæmolytic streptococcus can usually be isolated from the gums of an individual patient; (4) that more than one serological type can sometimes be isolated from the streptococci found in the blood immediately following the extraction of teeth.

Control blood cultures from persons with apparently healthy gums.—Blood cultures have been made from 30 healthy young adults without obvious dental disease. These were all negative. It may also be noted as an additional control to the technique of blood culture that in none of the 38 cases shown in Table I., Group C, as having no detectable gum disease, were organisms found in the blood cultures before extraction.

Discussion

From time to time cases of subacute bacterial endocarditis are met with which follow the extraction of one or more teeth. The foregoing observations indicate the source and mode of infection in such cases. The transient bacteriemia following operative trauma is analogous with that described by Barrington and Wright in catheter fever where *B. coli* was the usual organism isolated from the blood.

More interesting is the observation that in persons with severely septic mouths non-hæmolytic streptococci (mostly of the *viridans* type) may enter the blood stream in the absence of any obvious trauma. Owing to difficulties of access to patients our own observations on this point are very incomplete. We have been unable to ascertain whether the condition of "leak" into the blood stream in the positive cases is continuous, intermittent, or merely a fortuitous single occurrence. Nor have we yet determined whether minor degrees of trauma, such as brushing the gums or chewing, have any effect on the occurrence of the bacteriemia. There are, however, certain implications from which it is difficult to escape. From the nature of the technique it is likely that many cases in which streptococci enter the blood stream were missed. The efficient mechanism which exists for clearing the blood stream of organisms of low virulence no doubt only allows a "leak" of organisms into the circulation to be detectable in blood from an arm vein when the "leak" exceeds a certain magnitude or the organisms are abnormally resistant to phagocytic clearing. The small percentage of cases in which this non-traumatic "leak" was observed probably gives an under-estimate of the risk of streptococci entering the blood of persons with severely septic gums. The bacteriemia observed under these conditions is obviously not an infection of the blood in the ordinary sense but is rather a "leak" of relatively non-pathogenic organisms into the general circulation followed by their rapid removal by the phagocytic action of the body. It is generally admitted that damage or malformation of the valves is a frequent if not a necessary predisposing cause of subacute bacterial endocarditis. It is easy to imagine that the "leak" which is of little account in the normal person might determine the infection of diseased or malformed valves. At least the direct observation of such an invasion of blood as we have described provides a tentative explanation of how streptococci reach the heart valves in cases of subacute bacterial endocarditis and one in agreement with views which are widely held on theoretical grounds.

Summary

(1) Within a few moments after the extraction of teeth from obviously septic mouths, a transient streptococcal bacteriemia lasting a few minutes may be observed in 75 per cent. of cases. (2) Even in patients with mouths showing no obvious gum disease, extraction of teeth is followed by a transient streptococcal bacteriemia in 34 per cent. of cases. (3) Of 110 persons with septic mouths 10.9 per cent. were found to have a streptococcal bacteriemia irrespective of any operative interference. These observations were based on the examination of the blood on a single occasion. (4) The organisms isolated from the blood in the majority of cases were streptococci of the *viridans* type which were culturally and serologically similar to strains derived from the mouth. (5) The possible bearings of these

observations on the aetiology of subacute bacterial endocarditis are briefly discussed.

This work was carried out by one of us (S. D. E.) during the tenure of a grant from the Harmsworth memorial fund. Our thanks are due to Mr. J. L. Dudley Buxton, Mr. A. J. Chiappa Sinclair, and Mr. Arthur Bulleid for their kindness in supplying us with suitable cases for investigation, and to Sir Thomas Lewis, who placed hospital beds at our disposal.

ACHOLURIC JAUNDICE

THE SERIAL ONSET OF ACUTE BLOOD CRISES IN AN ENTIRE FAMILY

By ANGUS M. SCOTT, M.D. Glasg.

ASSISTANT PHYSICIAN TO THE VICTORIA INFIRMARY, GLASGOW

SINCE Minkowski¹ first drew attention to this interesting disease, the classical clinical signs of acholuric jaundice have been so well described, by Dawson² and others, that mere repetition would be tiresome if not presumptuous. But, as it is far otherwise when we come to deal with the pathogenesis of the condition, particularly the acute hæmolytic crises which not infrequently complicate the picture, a report of such crises occurring serially in all four members of an affected family is considered warranted.

THE FOUR CASES

I

A. B., a girl aged 11, was admitted to hospital on Feb. 22nd, 1934, in a severely collapsed condition.

History of illness (from mother).—On Feb. 19th the girl complained of headache, felt cold, shivery, and sick, but did not vomit. This continued for the next two days when she had no pain apart from the headache. On the 22nd she vomited once: the vomitus was bile-stained but contained no blood. She felt weak and giddy and fainted three times, complaining of visual disturbance when she recovered from these syncopal attacks. She had a motion of the bowels on Feb. 20th which appeared to be normal, and there had been no motion since then. The patient had always been pale but her mother thought that the pallor had increased during the past 12 months, following an attack of jaundice when she had been sick and vomited bile-stained fluid. She had a similar attack three years ago when she was jaundiced for three weeks.

No history of cough or spit, no urinary upset, and there had been no bleeding of any kind.

Condition on admission.—She was found to be a well-formed but rather thin girl with a mongoloid cast of countenance; definite but not marked jaundice of skin and sclerae. She looked pale, ill, and obviously very weak. Temp., 98.8° F.; pulse-rate, 132; resp., 28. The tongue was pale and dry but clean. Teeth were excellent and the fauces normal. The abdomen was symmetrical and moved freely, and there was no tenderness or rigidity. The liver was just palpable and the spleen was felt as a firm smooth tumour 3 inches below the costal margin, on deep inspiration. There was no swelling of lymphatic glands in any area. The heart sounds were poor in quality and a blowing systolic murmur was heard at all areas. Examination of the lungs and nervous system revealed nothing abnormal. Both fundi were pale but showed no hæmorrhages. The urine contained urobilin in excess but was otherwise normal. There was no mæna but the fæces were a deep brown due to excess of stercobilin.

Blood picture on admission.—Erythrocytes, 1,000,000; leucocytes, 7600; colour-index, 1; halometer reading,

6.4 μ ; fragility was increased, the range being from 0.5 to 0.45, and the van den Bergh gave a negative direct but positive indirect reaction. Stained films showed anisocytosis and microcytosis, most of the red cells having the typical deeply stained bulging appearance. No reticulocytes were seen. Differential count:

Polymorphs . . 57% Eosinophils. 3% Large monos. . 5%
Lymphocytes . 20% Basophils . . 3% Myelocytes . . 12%

Course of illness.—During the next 48 hours the girl's condition became highly critical with increasing pallor, dyspnoea, and delirium. The temperature was 101° F., pulse-rate 140, and respirations 34, and in an effort to save her life she was transfused on Feb. 24th with 16 oz. of citrated blood. There was no immediate improvement in the clinical condition, but ten days later, while the jaundice was much more obvious, the pallor was less marked, although the child was still very ill and blood examination revealed no reticulocyte response. During the next four days her condition improved gradually and the spleen diminished *pari passu* with this improvement. Convalescence was slow and was interrupted on March 18th by an attack of perisplenitis accompanied by a sharp rise of temperature to 102° F. associated with acute pain over the enlarged spleen and audible friction.

The progress of the blood condition is shown in Table I.

TABLE I

Hb. = hæmoglobin. R.B.C. = red blood-cells. W.B.C. = white blood-cells.

II

B. B., aged 9, sister of the first patient, was admitted to hospital on March 4th, 1934, as an urgent case of collapse with the following history. She had always been pale with a slight icteric tinge of skin and sclera but had never been grossly jaundiced. Apart from this she had enjoyed good health and had missed very few days at school. On the morning of March 3rd, 12 days after her sister took ill, she looked pale and on rising from bed fainted and was unconscious for a short time. She fainted again in the evening and was very weak. Next day she felt slightly better but complained of headache and was very restless. This continued until the night of March 5th-6th when she became delirious and vomited continuously. Bowels had been regular and there was no evidence of gross mæna. No history of cold in the head or exposure to infection.

On admission she was found to be a well-nourished child for her age, definite greenish-yellow, or "daffodil," tinting of the skin and sclerae. Her temperature was 100° F., pulse-rate 152, and respirations 40 per minute. Her breathing was rapid and shallow and she was desperately pale. She cried out in her delirium and presented some of the features of the typhoid state. The tongue was clean and the teeth were good. The palatal arch was high and the mucous membranes very pale. The fauces were normal apart from the pallor. The liver was not palpably enlarged, but the spleen was just felt below the costal margin. There was no obvious enlargement of the lymph glands. A soft blowing systolic murmur was heard all over the precordium and a very short diastolic murmur was audible over the sternum. The pulse was small, soft, and rapid. The urine contained urobilin in excess and a slight trace of albumin.

Examination of the blood showed: erythrocytes, 820,000 per c.mm.; hæmoglobin, 16 per cent.; colour-index, 1; leucocytes, 11,000; halometer reading 6.3 μ ; fragility range, 0.45-0.35; no reticulocytes were seen. Stained

films showed marked microcytosis, with well-stained red cells of globular shape; slight poikilocytosis. Many normoblasts and a few megaloblasts were seen. Differential count:

Polymorphs .. 72% Eosinophils. 3% Large monos.. 5%
Lymphocytes . 14% Basophils .. 1% Myelocytes .. 5%

Her serious condition calling for immediate transfusion, she received a pint of citrated blood, and showed an immediate and marked improvement: temperature 98.4° F., pulse-rate 102, respirations 20. Table II. shows the progressive improvement in the blood condition.

III

C. B., aged 5, a younger brother of the two previous patients, was admitted to hospital on March 11th, 1934, for observation in view of the experiences of his sisters. At birth, and for six months after, he had been jaundiced and had always been pale. He enjoyed fair health in spite of his pallor and has never again been noticed to be jaundiced. On March 8th, 15 days after A. B. and five days after B. B., he complained of feeling unwell. He felt tired and languid but had neither headache nor digestive upset.

On examination: Temp., 101.8° F.; pulse-rate, 140; resp., 28. He was found to be a small poorly developed boy, extremely pale, and with a slight icteric tinting of the skin and sclerae. He showed no cyanosis, oedema, or dyspnoea, but had a bright malar flush. Mentally he was very bright but rather nervous. Fauces were normal, but the palatal arch was high and his teeth were badly decayed. There was slight general tenderness over the abdomen without rigidity. The liver was not palpably enlarged, but an enlarged, smooth, firm spleen could just be felt. There was no obvious enlargement of the lymphatic glands. The pulse was regular in rhythm, rapid and of small volume and low tension. There was conspicuous precordial pulsation and soft systolic murmurs were heard at all areas. Nothing abnormal was detected in the respiratory or nervous system. The fundi were pale but showed no hemorrhages. The urine contained an excess of urobilin and later an occasional faint trace of albumin.

TABLE III

Van den Bergh: +ve indirect on each date.

Date.	Hb.	R.B.C.	W.B.C.	C.I.	Reticulo- cytes.	Fragility range.
Mar. 11	(p.c.) 23	850,000	4,200	1.3	(p.c.) 2	0.45-0.35
" 12	20	810,000	4,800	1.2	2	0.65-0.45
" 13	18	800,000	5,000	1.1	2	"

" 15	25	1,500,000	10,000	0.83	10	0.45-0.35
" 25	41	2,780,000	12,000	1.0	15	
Apr. 9	45	3,200,000	5,200	0.7	8	0.65-0.45

Blood examination showed: erythrocytes, 850,000 per c.mm.; leucocytes, 4200; haemoglobin, 23 per cent.; colour-index, 1.4; halometer reading, 6.3μ; reticulo-cytes, 2 per cent.; fragility range, 0.45-0.35; van den Bergh indirect positive. Films showed microcytosis, macrocytosis, and an occasional normoblast.

Hepatex P.A.F. was given intravenously for the next two days but as anticipated there was no improvement in the blood picture or the clinical condition, and again transfusion had to be resorted to on March 14th when

he received 10 oz. of citrated blood. Table III. shows the subsequent improvement in his condition.

IV

On March 15th D. B., a boy of 7, and the last member of the family, was, like the previous patient, admitted for observation and investigation. He had always enjoyed fair health, had never been noticeably jaundiced, and had taken a very active part in all the games at school. Recently his mother had noticed that he was short of breath on slight exertion and his colour was not so good. On March 12th, four days after his younger brother, he was obviously tired and listless but made no complaint.

On examination he was seen to be a well-developed but pale boy with a slight icteric tingeing of the skin and sclerotics. There was no cyanosis, oedema, or glandular enlargement. Tongue was clean, teeth good, and nasopharynx normal. The liver was not palpably enlarged and the tip of the spleen could just be felt below the costal margin, being smooth and firm and not tender. The pulse was regular in rhythm, of low volume and poor tension. The heart sounds were of fair quality, but a loud blowing systolic murmur was heard all over the precordium and of maximum intensity at the base. Respiratory and nervous systems were apparently normal. On admission his temperature was 98.4° F., his pulse-rate 128, and his respirations 28 per minute. His urine contained urobilin in excess and his faeces had the usual "cocoa powder" reddish-brown colour.

His blood picture on March 11th, four days before admission, showed: erythrocytes, 2,600,000; leucocytes, 8900; haemoglobin, 58 per cent.; colour-index, 1.1; halometer reading, 6.2μ; reticulo-cytes, 2 per cent.; fragility range, 0.55-0.45; van den Bergh indirect positive.

Here again in an effort to stave off the apparently inevitable crisis, intravenous hepatex was administered but without effect. He was transfused two days after admission, receiving 15 oz. of citrated blood, with an immediate improvement in his clinical condition. Stained films showed the usual dark-staining microcytes, many megalocytes, and numerous normoblasts. The progress of the blood picture may be seen from Table IV.

June 23	50	3,200	6,500	0.75		

This boy's convalescence was interrupted by an attack of acute tonsillitis on March 28th, which had an obvious slowing effect on his hemopoiesis.

FAMILY HISTORY

Mother and father enjoy good health but the father (Mr. B.) has always had a "curious" complexion and gave a history of having been admitted to hospital in 1929, following an attack of what may have been biliary colic when it was discovered that he had an enlarged spleen. At that time his blood picture showed: erythrocytes, 5,300,000; leucocytes, 8500; haemoglobin, 80 per cent.; colour-index, 0.75; but his fragility range had not been investigated.

When he came to hospital in connexion with the admission of the first patient his complexion at once confirmed the provisional diagnosis of hemolytic family jaundice.

On examination Mr. B. was found to be a slimly built man of 45 with a curious café-au-lait complexion. There was definite icterus of skin and sclerotics. The liver was 2 inches below the costal margin and the spleen was felt as a hard, firm tumour 3 inches below the costal margin,

but there was no tenderness over either organ. There was no evidence of leg ulceration or skeletal changes.

Blood examination (March 10th) showed: erythrocytes, 3,600,000; leucocytes, 11,000; hæmoglobin, 80 per cent.; colour-index, 1.1; halometer reading, 6.2 μ ; fragility range, 0.6-0.45 per cent.; van den Bergh—a delayed direct and positive indirect.

He is the youngest of a family of nine—six brothers and two sisters, one brother having died in infancy (cause of death not known)—and states that his father also had what came to be called the "family" complexion. One sister and one brother are known to have enlarged spleens and the former shows an increased range of red cell fragility, but these two enjoy good health as do the other members of the family, and there has been no history of any parallel happenings in their families.

Mrs. B., the mother of the four children described above, is a healthy looking woman of 40, and her blood picture showed: erythrocytes, 3,900,000; leucocytes, 6000; hæmoglobin, 79 per cent.; colour-index, 1; fragility range, 0.45-0.35 per cent.; van den Bergh—both reactions negative. She has never been jaundiced.

COMMENTS

During their stay in hospital, when they had obviously recovered from the acute hæmolytic crisis, the four patients presented many features in common. Their colour varied from day to day—from hour to hour almost—and the same applies to the degree of splenic enlargement. In this connexion it seemed to me that, after they had passed the critical stage of the illness, they appeared to be better clinically when their spleens were relatively large, and this, I think, is what one would expect.

There was no evidence clinically or radiologically of the "tower-shaped" skull or other skeletal deformity described by Günsslen² and others, but the palatal arch seemed to be higher than normal in all four. One (A. B.) had a mongoloid cast of feature due to the smallness of the palpebral fissures and the angle at which they were set. Her sister (B. B.) had crowding and malformation of her teeth, which however showed no sign of caries. The blood Wassermann was negative in all four patients. They all passed huge bulky motions, particularly after their transfusions, and these showed the characteristic dark brown colour due to excess of stercobilin.

The girls were dismissed from hospital on May 18th and the boys on June 7th, on the understanding that they were to undergo splenectomy in the near future, to which their parents very bravely agreed.

DISCUSSION

So far as I am aware serial crises in hæmolytic family jaundice have not figured prominently in the literature. Vaughan,⁴ in discussing the ætiology of acholuric jaundice, mentions the case of a father and son who fell acutely ill on the same day and were admitted to hospital with a diagnosis of food poisoning or septicæmia. More recently Murray-Lyon⁵ reports the case of two brothers whose story is quite parallel to my series except that the question of Lederer's anaemia was raised because of the low reticulocyte count in the elder of his two patients. But that the low reticulocyte count is evidence that hæmopoiesis is failing to keep pace with the rapid blood destruction is well seen in Table IV. of this series when the patient was admitted before the actual crisis occurred. As soon as the patient has been tided over the crisis, there is a marked rise in the reticulocytes. In each of the four cases described above the initial reticulocyte count was low and only rose when the crisis was over.

The release of what Vaughan⁴ aptly calls "the trigger mechanism" appears to be the most interesting feature of these crises. From the clinical description of these four cases it will at once be appreciated that no adequate cause, such as common infection, was discoverable. The parents were firmly of opinion that emotion played a large part in Cases II., III.,

and IV., and Piney⁶ states that "the onset of such crises is often preceded by psychic disturbances, such as rage." But if we accept this "sympathetic" view of the onset in Cases II., III., and IV., we are still left with the difficulty of accounting satisfactorily for the onset in Case I.

I am glad to be able to record that all four children have since (September, 1934) been successfully operated on by Mr. Alexander McLennan in the Royal Hospital for Sick Children, Glasgow, and the effects of splenectomy on their blood pictures have been fully investigated by Dr. W. T. W. Paxton, whose results will be published in due course.

It gives me great pleasure to express my thanks to Dr. Douglas W. Russell, for permission to publish these case records. I am indebted to Dr. Archibald P. Robertson, our then house physician, for his painstaking work in connexion with the blood examinations.

HODGKIN'S DISEASE IN NATIVES OF NIGERIA

RESULTS OF THE BIOLOGICAL TEST

By E. C. SMITH, M.D. Dub.

SENIOR PATHOLOGIST, MEDICAL RESEARCH INSTITUTE, LAGOS

THE biological test for lymphadenoma, as described by Gordon,¹ is a valuable addition to the clinical and histological methods of diagnosis of this malady. The average Nigerian dislikes long periods in hospital and unless dramatic results ensue from treatment he is prone to return to his farm, usually far distant, and the native "doctor." It is often, therefore, impossible to keep such people under observation for long periods and clinical histories are either unreliable or are too meagre to be of any real value. The removal of a gland for examination is usually possible and is now done as a routine in suspected cases, and the diagnosis is based upon the histological findings combined with the results of the biological test in rabbits. Material from out-stations can be forwarded in phenolised broth (0.5 per cent.), as it has been shown by Gordon that the sensibility of the test is in no way impaired by the presence of phenol in this dilution.

The present paper is an attempt to summarise the findings from material from nine cases of lymphadenoma in Africans.

Diphtheroid bacilli have been implicated in the ætiology of Hodgkin's disease by Bunting and Yates² (1913) and in four of the cases under review an investigation was made for these organisms. In three instances the glands were received in formalin so that histological examination only was possible.

Age and sex.—No history was obtained with three of the tissues examined. Five of the patients were males, two being boys aged 10 and 14, and two adults, aged 25 and 35. The remaining one was an adult female.

Site.—Generalised enlargement was noted in three of the cases. Cervical enlargement only in one, cervical and axillary only in a second, inguinal and deep abdominal in a third.

Duration.—So far as could be ascertained from the scanty information available, the duration varied from six months in the abdominal and cervical cases, to three years in the one with cervico-axillary involvement.

FIG. 1.—Hodgkin's disease in an adult female. Asymmetrical cervical enlargement.

If several glands had been removed, one was immediately placed in Bouin solution for histological purposes. If only one gland was available, a portion was excised with sterile scissors and placed in the fixing solution; the remaining glands, or portion of a gland, were retained for bacteriological investigation. In the last three cases to be examined, material was preserved for the biological test also.

The bacteriological examination had a two-fold object, first, to exclude the possibility of infection with tubercle bacilli, and second, to show whether organisms of the diphtheroid group were present. To accomplish this a portion of the gland was ground up in a Griffith's tube with a few drops of nutrient broth, and when it was sufficiently emulsified, 0.5 c.cm. was drawn up into a syringe of a suitable size and inoculated into the mammary region of a female guinea-pig. Three animals were used for a test.

A further portion of gland tissue was ground up in a similar manner and the emulsion so obtained was inoculated direct, by means of a platinum loop, into flasks of 50 c.cm.

FIG. 2.—Left: a strain of diphtheroid organism isolated from patient (Fig. 1). Right: a ten-day culture of the same organism showing involution forms.

capacity containing serum- (sheep) agar. Anaerobic plates were then poured after the method described by Krumwiede and Pratt. Loopfuls of the emulsion were further stroked on to blood-agar and serum-agar slopes. This part of the technique was omitted in two of the cases investigated as it was found that these aerobic cultures always became overgrown with organisms of the spreading

type. In addition, a portion of the gland from each of the three last cases was ground up in a sterile mortar, a weighed amount (1.0 gramme) was diluted with nutrient broth in the proportion of one to five and was then stored at freezing temperature for five days. After this the emulsion was allowed to remain at 27° C. for one hour and was then further diluted with nutrient broth to 1 in 20 and

FIG. 3.—Photomicrographs of section of a gland from patient (Fig. 1) showing types of giant-cell encountered.

inoculated into rabbits in the manner described by Gordon. Two to four rabbits were used for each test. In one of these three cases, that in which there was enlargement of the inguinal and deep abdominal glands, some of the ground-up gland material, after drying in vacuo over calcium chloride, was transferred to a sealed tube and kept at 27–29° C. in the dark for one month.

HISTOLOGICAL EXAMINATION

Paraffin sections were prepared and stained by hematoxylin-eosin and by the Giemsa method. The accompanying photomicrographs illustrate the type of lesion found. All the characteristic features of lymphadenoma—i.e., the distortion of the normal glandular tissue, fibrosis, the presence of cells of an unusual form such as the Hodgkin type of giant cell, and infiltration with eosinophil cells—were present in varying degrees. Too much importance must not be attached to excessive infiltration with eosinophil cells when dealing with tissues from natives, since the coexistence of a filarial infection or of intestinal parasites is of frequent occurrence, and here a differential blood count is of value. Fibrosis was present to an extreme degree in an axillary node from a case (No. 25S/33) of generalised enlargement of the lymph glands. The fibrous tissue had proliferated so much that it replaced almost the entire substance of the gland. Here and there remained small groups of round cells with scanty multinucleate forms and a very occasional eosinophil. Dr. Gordon regarded this section as being very suggestive of "Hodgkin in the fibrotic stage." The results of the biological test, described later, are of particular interest. Unfortunately it was not possible to follow up this case clinically. It is worth noting that, in macroscopic section, the glands in the earlier stages

of the disease presented a typically homogeneous, faintly lobulated surface of a deep yellow colour, as contrasted with the dense white appearance exhibited by glands affected with a true neoplastic growth.

FIG. 4.—Photomicrographs showing types of lesion seen in sections. Above: area of necrosis with polymorph cell infiltration. Below: fibrotic area with well-marked giant cells of the "foreign body" type.

BACTERIOLOGICAL EXAMINATION

The inoculated guinea-pigs were examined at weekly intervals up to three months. Local induration and slight swelling of the region occurred in all of the animals within the first month. The swelling and induration gradually subsided and when the animals were examined post mortem no evidence of tuberculous or other infection was found.

Anaerobic plate cultures.—After two days' incubation at 37° C. the cultures were examined with a binocular microscope and by transmitted light. Three types of colony could usually be distinguished.

(a) Large dense lens-shaped colonies composed of Gram-positive cocci, presumably staphylococci.

(b) Pale translucent irregular or polyhedral-shaped colonies (composed of Gram-negative rod-like bacilli).

(c) Minute lens-shaped or rounded colonies, composed of Gram-positive bacilli showing well-marked beading when stained by Giemsa and resembling in general the text illustration given in Ford² of *Corynebacterium hodgei* (Bunting and Yates).

Colonies of this third type were fished from the plates and were subcultured upon serum-agar and upon blood-agar slopes, the latter containing potassium tellurite. Minute colonies were observed within 48 hours, those on the media containing potassium tellurite being of an intense black colour. Further subcultures, made upon serum-agar, yielded more rapid growths; colonies, visible to the naked eye, being obtained within 12 hours. In four-day and

ten-day cultures, maintained upon the same medium, the organism showed well-marked pleomorphism, beading, and involution forms.

EXPERIMENTAL INOCULATION OF THE ORGANISM INTO ANIMALS

Cultures of a strain of the diphtheroid organism, obtained in the manner outlined above, were used for experimental inoculation into guinea-pigs, rabbits, and monkeys (*Macacus rhesus*).

Guinea-pigs.—Six animals were inoculated subcutaneously, the inoculum consisting in each instance of an actively growing 48-hour serum-agar culture washed off with approximately 1 c.cm. of nutrient broth. No pathogenic action was observed.

Rabbits.—Four animals were used. Two received subcutaneous inoculations, the inoculum being the same as for the guinea-pigs, and two received intravenous inoculations, each inoculum consisting of 0.5 c.cm. of a broth "washing." No pathogenic effects were observed up to a period of six months.

Monkeys.—Four *M. rhesus* were employed. Two received bi-weekly injections into the subcutaneous tissues of one axilla over a period of eight weeks. Two received weekly intravenous injections for a period of six weeks. The inoculum in each instance consisted of a broth "washing." The animals which received the axillary inoculations exhibited palpable glands in both axilla at the end of three weeks. No change was observed in the animals which had received the intravenous inoculations. A specimen of blood-serum was obtained from one of the monkeys at the end of six weeks and it was found to possess an agglutinating titre of 1/1440 for the strain of diphtheroid bacilli used for the intravenous inoculations. No agglutination was obtained with other strains of diphtheroid bacilli isolated from lymphadenomatous material. Living suspensions were employed in these agglutination tests.

One of the animals which had received axillary inoculations was killed and examined post mortem at the end of ten weeks. Symmetrical enlargement of the axillary nodes was found, the glands were soft and varied in size from a pea to a hazel-nut. They were embedded in vascular granulation tissue and showed no tendency to become adherent or to suppurate. Beyond slight enlargement of the spleen there was no other finding of note. Smears were made from the freshly cut surface of several of the enlarged glands and small fragments were inoculated upon serum-agar and blood-agar slopes. No organisms were seen in the smears when suitably stained and the cultures were negative after 48 hours' incubation at 37° C. Paraffin sections were prepared from a few of the larger nodes and were stained by hæmatoxylin and eosin. On section there was some thickening of the capsules of the glands and slight generalised fibrosis. The follicles were prominent and contained many cells in the process of mitosis. The reticulum was infiltrated with round cells, plasma cells in clusters (Pyronin methyl-green stain), and scanty polymorph cells. The condition in general suggested a non-specific inflammatory reaction. The other animal which had received axillary inoculations showed gradual regression of the glandular enlargement and six months later appeared to be normal.

METHOD AND RESULTS OF BIOLOGICAL TEST

The biological test was performed on three occasions with tissues received from cases thought to be suffering from lymphadenoma and on four occasions with material not originating from cases of Hodgkin's disease. A brief note on these "controls" may not be out of place.

In the first the material consisted of portion of a gland which had been removed from a young male native suffering from generalised glandular enlargement and swelling of the testis. The histological appearance suggested spindle-celled sarcoma, but the tissue was degenerate and difficult to stain. A biological test was made using two rabbits and the result was negative.

A portion of the testicular growth was obtained later and a part of this tissue was also used for a biological test, again with negative results. The histological appearances, however, left no doubt as to the true nature of the condition—i.e., sarcoma.

The third "control" consisted of tissue from multiple nodular growths of the skin. The histological structure was typical of the type of sarcoma known as Kaposi tumour. The biological test was negative.

The fourth control from a case at autopsy consisted of enlarged abdominal glands. Histological study of the spleen revealed an advanced form of sickle-cell anaemia. The biological test (three rabbits employed) was negative.

In two of the tests with material from suspected cases of lymphadenoma, typical results were obtained, the rabbits coming down with well-marked paralytic symptoms from the fourth to the seventh day following intravenous and intracranial inoculation of the material. Before the development of the typical paralysis with positive Romberg sign, a loss in weight, averaging 220 g., always occurred. It was also observed in positive cases that an animal placed on the floor in the usual sitting position, and suddenly turned completely round, always showed signs of loss of balance, being unable to regain control of its movements for 30 seconds or longer. The test, apart from its easy application, was found to constitute a reliable early indication of the progress of the condition. Material from one of the positive cases was, as already stated, kept in a sealed tube in the dried state for one month. It was then divided into two portions, one being sent to England where its potency for rabbits was confirmed by Dr. Gordon. The second portion was redissolved in a few c.cm. of nutrient broth and was then inoculated into four rabbits and two monkeys (*Macacus rhesus*). Two of the rabbits received intracranial inoculations only. All four rabbits developed typical paralysis on the fifth or sixth day after inoculation. The monkeys showed no evidence of having been inoculated.

The histological findings in these two cases fully confirmed the results of the tests in rabbits. It is interesting to note that, in one of the cases, sections prepared from the gland received were not typical of Hodgkin's disease. When the biological test gave a positive result with the remainder of this gland, a further specimen was obtained from the case. This second gland was considerably larger than its predecessor and presumably the condition was in a more advanced state since the histological appearances were now characteristic of lymphadenoma.

The third case (258/33) must be regarded as doubtful, both from the histological findings, already noted, and from the results of the biological test.

The gland from this case was received in 0.5 per cent. phenol broth, having taken eight days to arrive from an out-station. Cultures were made from it on arrival on serum-agar and in nutrient broth and were found to be sterile after 48 hours' incubation at 37° C. The gland was ground up in the usual way, emulsified in nutrient broth in a dilution of 1 in 5, and after storing for 24 hours at freezing temperature the suspension was inoculated intracerebrally and intravenously into two rabbits. These remained apparently normal with no loss in weight for a period of 40 days from the date of the inoculations. They then showed a loss in weight of 210 g. and 250 g. respectively, they exhibited a swinging temperature varying from 100° to 104° F. over a period of four days, and at the same time they developed a typical spastic paralysis with an extremely well-marked Romberg sign. The animals took no food, were obviously in a cachectic condition, and were eventually chloroformed. At autopsy no gross lesion was found, cultures from the spleen and heart's blood were negative, and sections of the brain revealed no histological lesion beyond well-marked

congestion. A passage of brain material was then made into two rabbits and 12 white mice with negative results.

Though the results suggest an unusual form of delayed reaction the possibility of a spontaneous outbreak of some form of virus infection must be considered. Against this hypothesis, however, is the fact that the remaining stock of rabbits did not show any evidence of a generalised infection at the time.

SUMMARY

Eight certain and one doubtful case of lymphadenoma are reported from Lagos, Nigeria. In six of these the diagnosis was based upon histological findings alone, whilst in three the biological test was carried out in addition. The test was definitely positive in two of the cases. The third case was not typical histologically and must be regarded as doubtful. Tissues from non-lymphadenomatous conditions were used as controls for the biological test in four instances, the results being negative. Material from four of the cases under review was investigated for the presence of diphtheroid bacilli and the organism was isolated in all. Cultures of one strain of the organism were used for animal inoculations with negative results.

I am indebted to Dr. W. B. Johnson, director of medical services for Nigeria, for permission to publish; to Dr. M. H. Gordon, of St. Bartholomew's Hospital, London, for his kindness in personally demonstrating the technique of his test; to Prof. E. H. Kettle for his opinion on the sections from the cases reviewed; to the director of the Rockefeller Yellow Fever Commission for the use of the *M. rhesus* monkeys; and finally, to those medical officers who kindly sent material for examination.

A CASE OF CONGENITAL DEFECT OF THE STERNUM

By A. JORDAN, D.Sc. Strasbourg

A SYRIAN tobacco-planter, aged 60, fell down stairs and broke his right humerus. He was admitted to St. Bartholomew's Hospital under the care of the surgical professorial unit on Sept. 5th, 1934, when it was discovered that he had no sternum. He was a short, very fat man. All his life he had been aware that the skin on the front of his chest advanced and receded during respiration. This abnormality was not the result of accident. He did not know of any similar defect or other congenital anomaly in his family.

THE THORAX AND RESPIRATORY MOVEMENTS

During inspiration the skin over the sternum receded to such an extent as to cause a marked depression; during expiration it became slightly raised. The two sterno-clavicular joints could be palpated but between them no bone was felt. On each side the clavicle joined a bar of bone which descended as the well-defined lateral boundary of the deficiency, being joined by the costal cartilages of that side. The defect was continuous with the front of the neck above. Below the fourth costal cartilages it was not possible to determine the presence or absence of bone in the midline. The

pleurisy 24 times. Of these, 20 are well to-day. It does not appear, therefore, that this is a serious complication. In fact, it may be of great advantage [by serving as a collapsing medium, as the example related in Fig. I. shows. This patient is in excellent health to-day with no symptoms and no bacilli.

As it has been suggested that diathermy (D.) is

FIG. I.—Serial radiograms of female, aged 16. (A) Extensive disease with gross cavitation. (B) Incomplete and pneumothorax. (C) Adhesions cut. (D) Obliterative pleurisy commencing. (E) Fluid appearing. (F) This gradually increased in amount and was pushed up towards the apex, where it has remained unabsorbed.

more apt to produce an effusion than the electro-cautery (E.C.) the following figures are given:—

Type of current.	Times employed.	Fluid appeared.
E.C. alone	28	4 (14%)
D. alone	35	8 (23%)
D. and E.C. combined	47	12 (25%)

The differences in these figures are probably of little or no significance, as I have used the electro-cautery alone only for the easier and non-vascular adhesions.

Surgical emphysema occurred 42 times: slight 31, moderate 6, much 5.

Temperature Reaction.—Often there is no reaction at all. Frequently a slight fever occurs, 99° to 99.5° F., usually 24 hours after the operation and lasting for one day. Occasionally the temperature may rise to as high as 103° and become normal in three days. More prolonged febrile reactions have been experienced 15 times, including the empyema cases; in most instances the temperature was normal again in 5 or 6 days' time.

EMPHYEMA

Empyema has occurred 7 times.

Tuberculous	3 cases.
Mixed	3 ..
<i>Staphylococcus albus</i>	1 case.

The tuberculous empyemas were probably due to irritation of tubercles on the pleural surfaces.

one case a large caseating tubercle could be near the lung end of a wide adhesion, and I thought at the time it might cause trouble.

Of the 3 patients with this complication, one is alive and well; another alive and free from tubercle but with a sinus; the third (the patient with the large visible tubercle), after developing an acute empyema with high temperature, which was left severely alone and not touched except for the initial exploratory puncture, regained her health in a marvellous way was free from all symptoms and remained well till after the birth of a child 4½ years afterwards, when she declined and died.

The three mixed empyemas were due to spontaneous pneumothorax occurring respectively, four weeks, three days, and three months after the operation. All were hopeless bilateral cases from the start, and adhesion cutting was resorted to as a forlorn hope. In one case post-mortem examination revealed two perforations in the lower lobe, far from the site of the operation. Of these three patients, two are dead and one is dying.

The staphylococcus empyema came on fourteen

LEGENDS TO COLOURED ILLUSTRATIONS ON PLATE

FIG. II. shows an apical adhesion not far from the sub-clavian artery. It is a fairly wide band, fleshy and obviously containing lung tissue undesirably close to the chest wall. This being the case, the left-hand edge of the adhesion was nicked in order, it was hoped, to allow the adhesion to stretch.

FIG. III. shows the appearance at the second operation, when the adhesion was divided or enucleated on the chest wall. (Fig. IV.)

FIG. V. shows the scar perfectly white and bloodless.

FIGS. VI.—VIII. show what remained to be done after the second operation on Mrs. D. VI. and VII. illustrate two bands. The lower was membranous, attached to the mediastinum, with no free border mesially. It was left untouched. The upper, more fully illustrated in VII., was divided without difficulty near its insertion. VIII. shows what was left of a very large thick vascular adhesion. It had been half severed at the previous operation and the electrode had been pushed into the substance of the adhesion at its attachment to the parietal pleura at different points, and coagulated with diathermy, with the result that the adhesion could be severed with surprisingly little difficulty and no bleeding. The blood seen on the adhesion trickled down from one of the pricks of the local anæsthetic needle in

the parietal pleura, just outside the insertion of the adhesion.

FIG. IX. shows the retracted lung end of the divided adhesion.

FIG. X.—A folded adhesion with an irregular insertion. Great care must be taken to ensure that it has a free edge posteriorly. The Maurer's hook should be put behind and if the adhesion is too large to permit of this, it should be partly cut near the parietal pleura, and then further investigated. As it is impossible to know whether it contains lung tissue or not it must be divided piecemeal and continually re-examined.

FIG. XI.—It is better to cut the small adhesion first, lest it should tear out after the large adhesion has been severed.

FIG. XII.—A wide band adhesion, easily severable and without danger until the right-hand edge is approached, when lung tissue obviously runs up close to the parietal pleura. At this point the adhesion must be enucleated from the chest wall.

FIG. XIII.—A band adhesion which might contain lung tissue for part of its length. It is obviously fibrous, non-vascular, and easily severable. The smaller adhesion with its cone-shaped lung extension beneath is a much more difficult and dangerous problem. This must be enucleated.

DR. CHANDLER :

RADIOGRAMS ILLUSTRATING RETRACTION OF LUNG AFTER SEVERANCE OF ADHESIONS

FIG. XIV.

FIG. XV.

FIG. XVI.

FIG. XVII.

days after operation, when symptoms suggestive of spontaneous pneumothorax occurred. The empyema was drained by a closed method, the lung re-expanded, a thoracoplasty was performed, and the patient is now well.

One patient developed a streptococcal empyema eighteen months after the operation, as a complication of influenza. This was in no way caused by the operation.

It may be asserted, therefore, that in this series an empyema due to the operation has been of rare occurrence. The possibility of the occurrence of an empyema at all, however, is very disturbing and constitutes one of the main dangers of the procedure. Though correct and careful technique will doubtless keep the proportion of empyemas low, it is probable that if large complicated adhesions are tackled, it will be impossible to prevent entirely tuberculous empyema and spontaneous pneumothorax.

It is for this reason that judgment must be used and adhesion cutting not be resorted to indiscriminately or as a routine. A patient may look and be well clinically, but the persistence of a cavity or tubercle bacilli, because of adhesions, makes the prognosis so grave that thoracoscopy would be indicated. If however there is an incomplete pneumothorax because of adhesions, but the clinical condition is good, bacilli absent, and no cavity visible, we should surely be conservative in recommending adhesion cutting, even though we may feel unhappy about the ultimate result after the re-expansion of the lung, for we know that there is the possibility of converting a patient, apparently fit, into a very ill and toxic one.

HEMORRHAGE

Bleeding, in more than negligible quantities, has occurred fifteen times. Twice there was arterial spurting. The bleeding has always been controlled. Once a slightly blood-stained effusion occurred, but there has been no hæmothorax throughout the series. In every case, without exception, the hæmorrhage has taken place from the parietal pleura or the parietal end of the stump. The greatest possible preventive care has been taken by always coagulating before cutting, using the electro-cautery alone only on non-vascular adhesions, and by, as it were, whittling

down the adhesion piecemeal, rather than resorting to bold and spectacular cuts. Bleeding has become progressively more rare throughout the series.

Illustrative Cases

The following four cases may serve to illustrate the possibilities of pneumolysis. All were desperately ill before the intervention.

1. Sylvia, aged 7, in 1930 had acute tuberculosis of the left lung, which rapidly became excavated until a very large cavity was formed in the left lower lobe. Sputum was copious and always contained tubercle bacilli in large numbers. An artificial pneumothorax was induced, but the cavity was unaffected owing to large lateral adhesions. These were divided by the single instrument, when a perfect "collapse" of the lung was obtained. The cavity closed and the child became well. As she dreaded and hated the pneumothorax refills an oleothorax was made. She has remained perfectly well, and to-day, more than five years later, is living the normal life of a schoolgirl.

2. Mrs. B., aged 44. Bilateral tuberculosis of the lungs, slight right, extensive left, with a very large cavity. Left pneumothorax induced September, 1929. Cavity held open by a number of adhesions to left upper lobe. These were severed with considerable difficulty in three separate operations. After the second operation there was considerable surgical emphysema. During the third operation

there was much bleeding which was controlled by diathermy; a temperature of 100° F. for three days and some fluid. The fluid increased and had to be aspirated several times. The patient to-day, nearly six years after, is in excellent health, tubercle bacilli have never reappeared. The pneumothorax is still being maintained; fluid is no longer present, but there is a great thickening of the pleura. First two operations single instrument employed, third operation two instruments.

3. Miss C., aged 25. Cough, sputum, hæmoptysis, temp. 100° F., sputum T.B. plus, a very large cavity in the right upper lobe. Artificial pneumothorax was induced in March, 1933, but wide and thick lateral adhesions prevented the closure of the cavity. These were severed by the single instrument in one operation: there was no reaction. The cavity gradually closed and the patient made a complete recovery. The pneumothorax was terminated by December, 1934. The patient is in good health to-day.

The fourth case is related in more detail to serve as a record of operative technique.

EXPLANATORY TRACINGS OF SKIAGRAMS

(see opposite page)

FIG. XIV.—Right upper lobe riddled with cavities held up by numerous adhesions to pleural dome.

FIG. XV.—Complete freeing after adhesions severed by single instrument, with excellent result clinically.

FIG. XVI.—Left upper lobe almost excavated by a large cavity held out by a wide band lateral adhesion and a smaller mesial adhesion.

FIG. XVII.—Appearance after complete division of adhesions by the single instrument. The large stump of the lateral adhesion can be seen plainly. Good clinical result.

4. Mrs. D., aged 24. Tuberculosis, left upper lobe, high fever, flushed cheeks, night sweats and wasting, hæmoptysis, cough and sputum excessive, tubercle bacilli constantly present, almost the whole of the left upper lobe excavated. Artificial pneumothorax induced October, 1934. The upper lobe was held out by a number of adhesions of varying width and thickness. These were severed in three separate operations.

First operation (30.xi.34)

Single instrument, diathermy and electro-cautery. Point of entry second space, just outside the mid-clavicular line.

A band was seen at least three inches wide, the left-hand part from the operator's point of view, thin and membranous but very vascular, with thicker columns; the right-hand part and edge was thick and extended backwards to an unknown and unseeable distance. More mesially and anteriorly a cord appeared. No more could be seen with the direct-vision telescope. With the right-angled telescope another band adhesion, still more anteriorly, thin, translucent, and very vascular, came into view.

The outer half of the wide adhesion was anaesthetised, coagulated by diathermy, and cut by electro-cautery. This revealed an extensive posterior ramification of the adhesion, which was thick and fleshy. The cord adhesion was then cut by electro-cautery without anaesthesia. Much oozing occurred from the parietal stump. This was coagulated by diathermy. Then the left-hand edge of the broad adhesion was tackled, anaesthetised on the pleura, coagulated and cut with electro-cautery. Much oozing occurred, even from the preliminary pricks of the anaesthetising needle. This oozing was finally controlled with the small diathermy knob.

Time taken, nearly 1 hour.

Reaction.—Temp. 99° one evening, i.e., on the second day, otherwise none.

Second operation (28.xii.34)

Two instruments were used, diathermy and electro-cautery. Light, third space, just outside the anterior axillary line. Instrument, fourth space, between the mid-axillary and post-axillary line.

The large adhesion was easily found in this position and kept in view with the right-angled telescope. After cutting for some time, finding it impossible to see round the edge with the right-angled telescope, which kept getting obstructed by a more anteriorly inserted adhesion, a direct-vision telescope was put through the instrument cannula, when the adhesion could be beautifully seen, end on, and was found to be free and severable. The instrument was, therefore, inserted through the other cannula, and working left-handed the whole of the adhesion was severed. This revealed another adhesion further on, partly membranous, with several vascular columns. This was anaesthetised, the two edges were burnt through and part of the centre; the rest of the parietal insertion was coagulated and then left.

Time taken, about 1½ hours.

Reaction.—Temp. 100° next evening, 101° second day, 100.8° third day, 99° the fourth and fifth days, then normal. No other reaction.

Third operation (18.i.35)

The light was put in a lower space, and further out as previously decided, the instrument, posterior to the posterior-axillary line, in the sixth space. The cannula had to be pushed rather hard down on the skin, but it sufficed to deal with all the adhesions. Firstly, the middle fish-tail band insertion was cut. This was membranous and resisted the diathermy current. Then a cord was severed to the right-hand side of the thick band which was left from last time. Then this band was tackled and severed without great difficulty, it having been previously coagulated throughout. For some reason I could not get Maurer's hook behind it. I did not persevere much because it hurt the patient, but it appeared to be perfectly free. The whole adhesion was cut. Attention was then directed to the one that came forward and mesially towards the mediastinum. This looked like a thin translucent membrane, but on lifting up the edge it was found not to be free at all, but lung

tissue appeared to go right up to the mediastinum. No attempt, therefore, was made to cut this.

Reaction. Temp. 100.4°, 100.2°, 103.6°, 101.2°, 99.2°, 99.2°, 98.4° on successive days, then normal; slight fluid. No other reaction.

An excellent lateral collapse of the lung was obtained. The cavity and all symptoms and tubercle bacilli disappeared. The patient is in good health and has gained three stone in weight. Obliterative pleurisy is occurring and an oleothorax may be necessary to prevent the premature expansion of the upper lobe. The third stage of the operative procedure is illustrated in colour (Figs. VI.-IX.).

As it is difficult by verbal description for one worker to convey to another exactly what he is doing inside the chest and what types of adhesion he considers operable, unless they are working together, I submit certain coloured illustrations which were made by Mr. Shiells at the time of the operation. They will give some idea, though a limited one, of the structures encountered, but it should be realised that the picture the operator most desires will often be missed as it is usually impossible for him to know beforehand with what problems he is about to be confronted, and therefore difficult to know when to invite an artist.

The value of collapse therapy, so called, is indispensible. Too frequently it fails because of adhesions. If internal pneumolysis is or can be made safe, not only does it enlarge the scope of pneumothorax treatment, but it becomes the logical procedure whenever there are adhesions that can be divided. Pneumolysis will then be employed more often.

PERFORATION OF THE TUBERCULOUS INTESTINE IN PULMONARY TUBERCULOSIS

A REPORT OF TWO CASES

By DAVID B. ROSENTHAL, M.D. Melb.,
M.R.C.P. Lond.

MEDICAL SUPERINTENDENT, GRESSWELL SANATORIUM,
MONT PARK, VICTORIA, AUSTRALIA

ABDOMINAL complications in pulmonary tuberculosis are by no means rare, and are often present when the clinical picture points only to intrathoracic infection. Boyd¹ states that "every case of pulmonary tuberculosis which does poorly, but with no increase in the physical signs, should suggest intestinal involvement."

At autopsy, ulceration of the intestine, due to the tubercle bacillus, is frequently found, the figures varying from 30 per cent. to 80 per cent. Kaufmann² writes that "secondary intestinal tuberculosis is found in about 90 per cent. of cases of chronic pulmonary tuberculosis." On the other hand, very extensive destruction of lung tissue may be present in chronic pulmonary tuberculosis without intestinal ulceration. Nevertheless, perforation of the tuberculous ulcer is, by virtue of the thickened base of the overlying peritoneum, a pathological rarity. On this, Kaufmann says: "Perforation generally speaking is rare, and occurs only in acute annular ulcers which undergo quick caseation. The opening is circular, sharply cut, and usually small. The perforated loop is usually in the lowest part of the pelvis, if of the ileum, which is most frequently the case."

Muir⁴ and Boyd¹ agreed that perforation is relatively uncommon, and differentiate between

complete and incomplete perforations. Allen⁵ refers to "a rare example of perforation in the base of tuberculous ulcers in the jejunum," and remarks that perforation probably occurs only in cases of rapid course, with mixed infection.

Tuberculosis of the appendix is probably fairly common in intestinal tuberculosis (Muir) (Kaufmann), but perforation of the tuberculous appendix is rarely recorded. Kaufmann³ however states that "perforation (of the appendix) is not rare in tuberculosis."

The following cases illustrate unusual termination of advanced pulmonary tuberculosis: (1) complete perforation of tuberculous ulcer of the intestine; and (2) perforation of a tuberculous appendix.

REPORT OF CASES

I. COMPLETE PERFORATION OF A TUBERCULOUS ILEAL ULCER

A man aged 39, a hotel employee, was admitted to Gresswell Sanatorium on August 6th, 1934, suffering from pulmonary tuberculosis. He had suffered from weakness and cough (for two years), "nerves," which caused his abandoning work two months previously; and dyspnoea (for three weeks); he lacked energy and had frequent night sweats. The bowels were regular. He was told he had sugar in his urine. Sputum contained tubercle bacilli five weeks previously. He had lost 1½ st. in past six months.

Examination.—He was emaciated and obviously acutely ill, with dyspnoea on slight exertion. Heart: not enlarged; reduplication of second sound at apex, with systolic aortic murmur. Abdomen: liver edge palpable below right costal margin, otherwise nil abnormal. Central nervous system: normal. Lungs: extensive bilateral infiltration, with excavation of upper part of left lung, where many coarse râles were audible. On August 7th the blood sedimentation index (Cutler) was 28 mm. Urine: acid; specific grav., 1016; no sugar; trace of albumin; microscopically clear. Radiography (August 8th) showed "extensive broncho-pneumonic consolidation, involving practically all areas of both lungs, with cavitation in both apices. Small amount of relatively normal lung tissue at the base of the left lung. Gross distortion of the mediastinal shadow, together with marked 'tenting' of the left half of the diaphragm. Trachea deviated to the left side." On August 9th the sputum contained tubercle bacilli.

Progress.—August 13th: patient complained of diarrhoea, alternating with constipation. Partial response to symptomatic treatment and light diet. Sept. 9th: complaint of vague abdominal discomfort. Oct. 1st: gradually becoming worse, and now very ill; abdomen somewhat distended, but very little pain; motions, one or two daily (not blood-stained); distension partly relieved by enema. Oct. 2nd: abdominal distension not relieved by enema. Oct. 3rd: death.

Over the first two months the temperature ranged from 99° F. in the morning to 102° F. in the evening. On the evening of Oct. 1st, 1934, it rose to 103°, and then fell suddenly.

Autopsy.—Extreme emaciation; great abdominal distension. Right lung: weight 26 ounces; general pleural adhesions, both old and recent pleurisy; generalised broncho-pneumonia, most heavily affecting the middle third of lung, but scattered throughout; a few small cavities in the apices of both upper and lower lobes. Left lung: weight 30 ounces; general pleural adhesions; excavation of upper part of upper lobe, with remainder of the lung heavily sown with broncho-pneumonic patches, and showing multiple cavitation, particularly in the apex of the lower lobe, which was honeycombed. Heart: weight 9 ounces; small, "fibrous" changes in myocardium; valves competent.

Abdomen: peritoneal cavity distended with gas, of "heavy" odour but not offensive; peritoneum showed chronic inflammation, with free fluid, thinly purulent in type; much lymph present in flakes on bowel and other viscera.

Examination of the gastro-intestinal tract showed extensive ulceration of lower part of small intestine, many ulcers being almost completely circumferential, but no obstruction was observed. The base of one ulcer in the upper part of the ileum was perforated, the opening being about the size of a pin's head; the perforated loop was low in the pelvis. The terminal ileum, appendix, caecum, and large intestine were apparently normal.

Liver: 72 ounces; pale and fatty, with some "nutmeg" changes. Spleen: 7 ounces, slightly mushy. Kidneys: each weighed 6 ounces; some atrophic changes. Intracranial contents not examined.

II. PERFORATION OF THE TUBERCULOUS APPENDIX

A man aged 42, a farmer, was admitted to the sanatorium on June 29th, 1934, suffering from pulmonary tuberculosis. Past history was irrelevant. Symptoms of present illness seemed to date back twelve months; they were loss of strength and energy, troublesome cough with fairly copious sputum (never blood-stained), and dyspnoea even on slight exertion. No pain in chest was noted; night sweats were irregular. Micturition was normal. Bowels had acted freely and frequently for the last 9–12 months, with periods of normality. At present there were thin, watery motions four times a day, but no blood seen. Appetite capricious. Had lost 3 st. in the last year.

Examination.—Very emaciated; cyanosis and dyspnoea at rest; greatly increased by slight exertion involved in chest examination. Heart: not enlarged; sounds faint, but clear. Blood pressure, 120/90. Abdomen: liver dullness one finger-breadth below right costal margin; no free fluid detected; no tumour palpable; no tenderness elicited. Central nervous system: normal. Chest: large, barrel-shaped; very little respiratory movement of chest wall, particularly on right side; breath sounds much diminished over right lung, with generalised bronchial breathing, and patches of tubular breathing in the subapical regions; many moist sounds heard, mainly coarse crepitant râles. Fingers showed clubbing.

The diagnosis made was of advanced fibrocaseous tuberculosis, associated with emphysema.

The urine was acid; sp. g. 1028; no albumin or sugar; urates present.

Blood sedimentation index on July 2nd was 14 mm. Tubercle bacilli were found in sputum on July 3rd.

The radiographic report (July 4th) was as follows: "Right lung is partially collapsed by pneumothorax, with several fine strands of adhesions to chest wall and marked 'pocketing' of adherent pleura in the costophrenic angle. The lung itself shows widespread infiltration, with generalised fibrosis and emphysema in the uncollapsed portion. The left lung shows widespread infiltration with fibrosis throughout, with some emphysema at the base. Trachea and upper part of the mediastinum are deviated markedly to the left." Close examination of the patient did not yield any information which suggested the time of occurrence of the spontaneous pneumothorax. He had not had a sudden attack of dyspnoea, and had never experienced pain in the chest.

Progress.—On July 10th the patient complained of anorexia and "acid" type of indigestion, attended by diarrhoea. There was no abdominal pain or discomfort. Some relief was obtained from the administration of a mixture containing bismuth and opium. On the 17th his general condition was rapidly deteriorating. Diarrhoea was troublesome, but there was no abdominal pain. Abdomen now slightly distended, with general tenderness over the lower half, but not localised. Sudden cyanosis and death occurred on the same day.

The temperature throughout was fairly consistent—98° F. in the morning and 102° in the evening, with terminal collapse.

Autopsy Findings.—Wasted man; slightly dilated venules on face. Right lung: weight 28 ounces; pleural adhesions at apex; lung bound down on its diaphragmatic surface; diffuse fine tuberculous broncho-pneumonia in lung tissue, showing considerable fibrosis and emphysema, with much black pigment deposit throughout;

On the following morning (April 28th) the patient felt much better, but the pulse was again poor and 160 to the minute. She was therefore given 10 per cent. glucose in saline (to one pint of which 7 minims of 1/1000 adrenaline and 5 c.cm. coramine were added) by the continuous drip intravenous method, one pint being given in three hours.

The pulse-rate dropped and the patient's general condition improved distinctly. By the time four pints had been given her condition ceased to cause concern. The intra-uterine pack was removed on the afternoon of the 28th, when 1 c.c.m. pituitrin was given. Progress was satisfactory until the evening of the 29th, when the temperature rose to 99° F. On the morning of the 30th flatulent distension of the abdomen made its appearance, but was relieved by turpentine enemata. On palpation the uterus appeared to be normal, and intramuscular Ernuten was ordered thrice daily.

The lochia was rather offensive and the patient was gradually propped up to promote natural drainage. On May 1st the lochia were very offensive and the temperature reached 102° F. Kharsulphan was given intramuscularly and Dettol douches ordered thrice daily. Intra-uterine glycerin was started on May 1st and continued daily. On May 2nd, while the lochia remained offensive, the temperature started to drop, her appetite improved, and there was a gradual return to normal health.

I have reported this case in some detail, because from the history given by the patient's doctor and by her mother (who was attending as a qualified midwife and in the circumstances a very reliable witness) the case appears to be definitely one of spontaneous inversion. The mortality of acute inversion of the uterus is about as difficult to assess as its frequency, but in treatment there seems to be a tendency to overstress the benefits to be derived from "masterly inactivity." Given suitable measures to combat shock, the early reduction of the inversion seems to be indicated, while this can still be done comparatively easily and the uterine tissues have not yet been unduly damaged.

My thanks are due to Dr. F. Cauchi, who administered the anæsthetic, and to Dr. H. Fuld, who gave the blood transfusion. I have also to thank Mr. R. A. Grant for permission to publish these notes.

"IDIOPATHIC" STRIÆ ATROPHICÆ OF PUBERTY

BY F. PARKES WEBER, M.D. Camb., F.R.C.P. Lond.
SENIOR PHYSICIAN TO THE GERMAN HOSPITAL, LONDON

In ordinary cases striæ atrophicæ or striæ cutis distensæ can be explained as representing a method of cutaneous accommodation towards distension (physiological or pathological) when the skin is relatively insufficient—that is to say, unable to adjust itself by its normal elastic distensibility. In such cases a relatively too rapid growth or increase in bulk of the parts below the skin, or a cause of chronic distension of some kind—such as a relatively excessive growth of subcutaneous fat, muscle, or bone (especially connected with puberty), mammary gland, the pregnant uterus, ascites, tumours, or subcutaneous œdema—leads to a splitting or cleavage in the deeper parts of the cutis, manifested on the surface by the appearance of striæ atrophicæ, which are at first generally red or purplish, and in time gradually become white and smaller as they heal up.

But here I wish to refer only to those case of striæ not due to stretching of the skin; that is to say, the cases in which striæ have developed apparently in the absence of any special distension—in the absence of pregnancy, ascites, tumours, subcutaneous œdema, excessive subcutaneous fat, and other usual causes. In such cases the ordinary growth of the long bones, muscles, and subcutaneous fat seems to be associated with some insufficiency of the cutis (with perhaps deficiency of elasticity) which prevents the skin from adjusting itself to the parts beneath, excepting by the process of multiple cleavage—that is to say,

by the formation of "striæ atrophicæ." Striæ of this mysterious kind occur occasionally in apparently healthy, and in even athletic, individuals about the period of puberty, the skin failing to keep pace with the normally rapid growth of certain parts of the body, such as the shoulders, pelvis, and thighs. In 1932 I saw typical small striæ in the upper arms and upper parts of the thighs that developed without

obvious cause in a muscular male student at an English university. Striæ, in the absence of the ordinary causes, are however still better known to occur in connexion with enteric fever (notably the "striæ patellares") and certain other infections, although even in such cases the selective distribution of the striæ, and whether they are symmetrical or more or less unilateral or not, as I have elsewhere endeavoured to explain, must be

Diagram showing position of the striæ on the patient's back and buttocks.

due partly to mechanical causes, such as the position of the patient in bed, arrangement of pillows, &c.¹

Striæ form a prominent feature in the clinical syndrome attributed by Prof. Harvey Cushing to pituitary basophilia or basophilic adenoma of the pituitary gland, and in 1932 I suggested that the relative insufficiency of the cutis, which is a part-factor in the causation of the cutaneous striæ in so-called "idiopathic" and post-infection cases, may be due to a temporary basophilic hyperpituitarism associated with the period of rapid growth at and following puberty.²

I have recently seen a remarkable example of *idiopathic striæ atrophicæ of puberty* in a rather thin, tall girl, aged 13½ years. She seems bodily and mentally developed two years or so beyond her age, a good tennis player, but somewhat lanky and "overgrown," and inclined to slouch with bent back when sitting at her school work. Her height is 167 cm. and her weight is 51.5 kg. She commenced to menstruate at 12 years of age and her mammae and pubic hair are fairly developed. She has a series of bright red transverse striæ ("vergetures") over her back from the level of the tenth vertebra downwards (see Figure). There are several older (white) striæ over the outer upper parts of both thighs and there are a few smaller red striæ over the left gluteal region. It should be noted that her mother has had white striæ on the outer upper portions of both thighs since puberty, though she feels sure that none of these striæ were ever red.

In the case of the present girl the red transverse striæ over the back were first noticed by her mother

¹ On this whole subject cf. Weber, F. Parkes: Unilateral Striæ Atrophicæ, Practitioner, 1917, xcix., 453; also Weber: Cutaneous Striæ, Brit. Jour. Derm. and Syph., 1926, xxxviii., 1, and in discussions, Proc. Roy. Soc. Med., 1924, xvii. (Sect. Derm., p. 45), and 1927, xx. (Sect. Dis. Child., p. 11).

² Weber, F. Parkes: Urol. and Cutan. Rev., 1932, xxxvi., 731. This suggestion is not the same as that which I made in a short paper on the Causation of Striæ Atrophicæ Cutis (Vergetures), Brit. Med. Jour., 1928, i., 255.

about Christmas 1934, when they are said to have looked like very thin scratches; at that time the patient had a slight attack of whooping-cough. In other respects she has enjoyed good health. The causation of these "idiopathic striæ atrophicæ of puberty" is unknown, unless my above suggestion on the subject is correct. Anyhow, the patient in question developed a tendency to the formation of such striæ at puberty, as her mother did, and probably her habitual stooping over her schoolwork has determined the position of the striæ—namely, on her back at right angles to the convexity of the bend. It is possible that the infection with whooping-cough played a part in the causation of the striæ (analogous to the better-known part played by enteric fever in other cases) in association with the somewhat precocious onset of puberty. The bright red stripes across her back were very annoying to the patient during summer at the seaside in regard to bathing.

A CASE OF EUNUCHOIDISM

By ERNEST H. CAPEL, M.D., M.R.C.P. Lond.

ASSISTANT MEDICAL REGISTRAR, MIDDLESEX HOSPITAL, LONDON

A MAN, aged 35, was admitted to the Middlesex Hospital in March, 1935, complaining of increasing weakness and continued growth in height.

Family History.—Both parents were Irish, quick-tempered, and heavy drinkers. The father died at 64 from cancer of the jaw; the mother at 45 from an accident. One of the mother's brothers is said to be very tall. The patient is the youngest but one of eight siblings whose ages range from 33 to 52. They are all healthy and all except one are married and have two or more healthy children.

Personal History.—No details of early years are known. He attended school from 5 until 14 and was rather above the average in ability and usually at the top of the class. On leaving school he was a metalworker until the age of 21, and for eighteen months a ship's steward. He then went back to factory work until three years ago, since when he has been a butler. His standard of work has always been satisfactory.

Previous Medical History.—Operation at 13 for double inguinal hernia, which recurred and was operated on again at 15. Asthma, due to sensitivity to straw, developed at the age of 23 but ceased when he gave up working with straw. He has fractured several bones at various times, but there is no reason to suppose that his bones are unusually brittle. Sexual interest has been normal, but diminishing during the past few years, and there has never been any homosexual inclination. Masturbation is stated to have occurred since childhood until quite recently. At 23 he married and had normal though infrequent intercourse. An erection was obtained followed by orgasm but there was never any emission. His wife never became pregnant.

History of Present Complaint.—The patient is still steadily increasing in height, and the feet and hands are also growing so that he requires progressively larger shoes. There has never been any growth of hair on the face, axilla, or chest, and the pubic hair, which first appeared at 18, has always been scanty and of female distribution. The voice has always been high pitched and has never broken. He feels the cold badly and prefers hot weather. During the past two years he has complained of exhaustion after quite moderate exertion. He has lost two stone in weight in the past year.

Examination.—Weight, 10 st. 6 lb.; height, 6 ft. 2½ in.; span, 6 ft. 9½ in. Temperature 98.4° F. and pulse-rate 70, both remaining normal during the stay in hospital. As can be seen in the illustration the patient was tall and thin with the limbs slender and excessively long in proportion to the body. The hands and feet were large in proportion and there was no tufting of the phalanges

such as is seen in acromegaly. The skull was normal in size and appearance and there was no enlargement of the jaws. Only six teeth were present, the others having been removed. They were in good condition. The skin was pale, fine, and dry and gave a prematurely aged appearance due to the presence of many small wrinkles. No hair, other than lanugo hair, was present except for that on the scalp and a scanty pubic growth. The external genitalia were very small, and the testes, which were both present in the scrotum, were about the size of cherry stones. Scars were present on the abdominal wall from the previous operations. Clinical examination revealed no abnormality in the lungs, heart, abdomen, or central nervous system. Blood pressure 130/80. The ocular fundi were normal and the visual fields full. Mentally he was of good average intelligence. He was quiet and retiring and very sensitive about his condition. He had frequent mild fits of depression.

Special Investigation.—Blood count: red cells, 5,370,000; hæmoglobin, 100 per cent.; colour-index, 0.9; white cells, 10,000; polymorphonuclears, 62 per cent.; lymphocytes, 27 per cent.; monocytes, 10 per cent.; eosinophils, 1 per cent. Basal metabolic rate, minus 20 per cent. Fractional test-meal: high free and total acidity—0.27 and 0.23 per cent. respectively. Aschheim-Zondek test negative. Blood-urea 17, and non-protein nitrogen 21 mg. per 100 c.cm. Glucose-tolerance test within normal limits. Resting blood-sugar 93, highest 135 mg. per 100 c.cm. half an hour after taking 50 g. of glucose. Radiography: no thymus shadow; calcified glands at both lung roots; lower end of radius and ulna, upper end of humerus, upper end of radius, acromion process, upper and lower ends of femur and upper and lower ends of tibia and fibula showed non-union of epiphyses; pituitary fossa small, but showing no other abnormality.

Photograph of the patient.

Tandler and Gross¹ apply the term eunuchoid to those human beings whose appearance is entirely that of castrates although their sex glands have never been removed, and they have divided them into two types, the tall and the obese. Zondek² states that obesity is one of the common characteristics and even in the tall type some degree of obesity is usually present (though it may be only relative) in the sites of predilection—the breasts, the mons pubis, and the hips. He regards excessive vertical growth as a feature distinguishing eunuchoidism from pituitary obesity, attributing it to delayed union of the epiphyses. Union usually occurs by about the thirtieth year. The limbs tend to be long and slender, the tubular bones long, and the skull small in circumference. The lower part of the body is longer than the upper part and the fingers may almost touch the knees. Genu valgum and pes planus are common.

In these patients the development of the generative system is deficient and the secondary sexual characters do not appear. Hair fails to grow on the face or body, the voice does not break, and the larynx remains small, soft, and cartilaginous. Sexual desire is usually absent though occasionally it is normal or even excessive (Bauer³). The skin is pale and thin and the muscles poorly developed and feeble. The heart and aorta are often small and the blood pressure low. The blood picture is usually

normal but may show a lymphocytosis and more or less mononucleosis (Guggenheimer ⁴). The basal metabolic rate may be diminished or normal. A persistent thymus is said to be found frequently and the thyroid may be enlarged. There is usually nothing to indicate any abnormality of the pituitary.

The aetiology is almost always obscure. Hypoplasia of the sex glands is always present and often the testes are undescended. As a rule it is impossible to assign a cause for this aplasia.

The case described is an example of the tall type and shows only slight relative obesity. The patient has most of the essential features of the condition; the presence of sexual desire with the ability to obtain an erection with orgasm is uncommon and interesting. That atrophy of the testis may follow injury to the spermatic artery, an accident which sometimes occurs during operation for inguinal hernia, is well known, and the history of operation for double inguinal hernia at the age of 13 and again two years later for a recurrence makes it necessary to consider

this as a possible cause. The rather late age at which the operation was performed, the extensive changes present in the patient, and the fact that the testes are small but not hard and fibrotic makes this explanation seem improbable. Treatment in this case has so far not been attempted. There is at present no potent male sex hormone available at reasonable cost, and the results of testicular grafting are of such a temporary nature that it was not considered worth while.

I wish to thank Dr. E. A. Cockayne for permission to publish this case, and the Courtauld institute of biochemistry and the Bland-Sutton institute of pathology for the biochemical and pathological investigations.

MEDICAL SOCIETIES

HUNTERIAN SOCIETY

Dr. W. BRANDER was unfortunately prevented from delivering his presidential address to this society on the

Challenge of the Chronic Sick

which was read in his absence by Dr. ANDREW TOPPING on Oct. 14th. The last half century, said Dr. Brander, had witnessed a great realisation of responsibility on the part of the public for the acute sick, but no informed person could hold that the provision at present existing for the care and treatment of adult chronic sick is on a level with our scientific knowledge of what is required. It would be convenient to consider the facts under four headings.

FOUR FACTORS IN THE SITUATION

1. *Development of Public Services.*—Most of the inadequacies of the treatment of the chronic sick were, he said, traceable to the obsolete Poor Law. It was true that the Elizabethan principle was simply to relieve the needs of the sick without reservations or limitations, but in practice the facts were in direct opposition to this principle. Those responsible for the institutional care of the chronic sick had little use for the misfits, the unfit and derelicts among the population. About 100 years ago Sir James Shuttleworth, assistant commissioner at Somerset House, reported on the parish workhouse in Norfolk in these terms:—

"It was the receptacle of age, vice, disease and infirmity. The aged and infirm and the infants were promiscuously mingled with sturdy, able bodied paupers, idiots and the sick, in groups which presented to the eye merely a picture of common misery or depravity. In such houses the aged and infirm were tormented by their co-mates in want, the sick were left to waste the wretched remnant of their lives with little care or sympathy; the able bodied pauper lounged in listless apathy with the idiot over the fire. The sexes could scarcely be said to be separated at night in the miserable and ill arranged apartments."

It was not until about 1865 that sick wards of workhouses were officially discouraged, and separate infirmaries built for the chronic sick. They were however not to remain for long in what was, very often, excellent accommodation. Owing to the demands

for admission of acute medical and surgical cases, the accommodation for the chronic sick was gradually curtailed and they were displaced once again into the sick wards of the mixed workhouses. Twenty-five years ago the proportion of acute to chronic sick in many of the poor-law infirmaries was 20 per cent. ; in 1930 the position was completely reversed—the proportion had risen to 80 per cent. At the present time the majority of the adult chronic sick patients chargeable to local authorities are treated in non-appropriated mixed institutions. In other words, being inmates of poor-law establishments, they are “paupers.” Buildings and equipment are often distressingly insufficient and inadequate. The fundamental fallacy in administration has been the assumption that the needs of the chronic sick were all alike and could be met by the simplest form of care. A survey made by the L.C.C. in 1931 of their transferred institutions showed that the facilities for the care of over 3000 chronic sick were insufficient, inadequate, and misused.

2. *Attitude of the Medical and Nursing Professions.*—It was, said Dr. Brander, well known that the medical staffs of voluntary and municipal hospitals sometimes objected to having beds in their acute wards occupied by chronic patients. This objection was often shared by the nurses. The presence of the chronic patients bars the way for the admission of more interesting acute cases. This feeling was in part due to a sense of futility in the treatment of the chronic patient. The treatment needed is so often dependent on social and economic factors over which the doctor rarely has control. Again, whether due to some defect in our system of medical training or other cause, medical students are dominated by what might be called the cult of the "acute." While an acute disease rouses whole-hearted enthusiasm, a chronic disease is apt to be regarded as more or less dull and uninspiring. In poor-law institutions mainly occupied by the chronic sick the visiting medical officer's round was often very casual; he frequently regarded the wards as museums in which the only interest lay in seeing occasionally a few rare diseases in their later and incurable stages. Under such treatment the chronic patients lost faith in doctors and nurses, and with the loss of morale their physical state deteriorated.

3. *Economical and Social Factors.*—In acute disease, social and economic conditions played only a minor

part; medical considerations are the paramount ones. In chronic disease the picture was different; the social and economic elements were closely associated with the purely medical, and were in most cases of greater importance. Because of his chronicity, if for no other reason, the patient's family suffers. Disorganisation, unemployment, destitution, and shattered morale result in the picture of the adult chronic invalid. The patient becomes such a burden on the children that they welcome any means to be rid of him.

4. *Difficulties in Administration.*—Municipal hospitals had to contend with many obstacles that do not affect the voluntary hospitals. One of them was the obligation to admit any poor person whose condition demands medical or surgical treatment, and who is unable to secure it elsewhere. Another obstacle was their inability to limit the number of patients. They could not discharge a chronic patient who needed institutional care unless there was room for him in another municipal hospital or institution. When the patient was likely to require prolonged medical and nursing care these difficulties led to the vexing "system of transfer," in which unfortunately the transfer was often dictated less by the needs of the chronic patient than by the pressing demands of the acutely ill patient.

MEDICAL ASPECTS OF CHRONIC ILLNESSES

He would not consider, Dr. Brander said, chronic mental diseases or pulmonary tuberculosis, because in each of these fields public responsibility had been recognised, and excellent provision made. The great undifferentiated group, known as the "chronic sick," included all other types of chronic disease. For the most part they were diseases of slow development; there was little homogeneous among the sufferers. Their disability was due largely to cardiovascular disease, diseases of the nervous system, non-tuberculous diseases of the lungs, rheumatism in its various forms, chronic kidney disease, diabetes mellitus, and other metabolic diseases. For most of these affections there was no permanent cure, although in many instances the disease might be arrested and the patient gain years of useful life.

Chronic disease affected persons of all ages, from the beginning to the end of life. Among the chronic sick were babies injured at birth and crippled by congenital defects; children under 16 years of age, and young adults with orthopaedic troubles, heart disease (congenital or acquired), rheumatism, or diseases of the nervous system; the middle-aged group, between 40 and 60 years, who constituted a very large proportion of those demanding hospital care; lastly, the aged, 70 years old or more.

Adequate treatment had been retarded in the past, he said, by two misconceptions regarding the nature of their disease: (1) chronic diseases had practically been labelled incurable; (2) they have been too closely associated with that decline in well-being which is called senility.

In spite of its grave significance, the term incurable had often been employed too lightly in the case of many chronic sick. As medicine progressed the conception of incurability was changing, and physicians and surgeons to-day were not slow in recognising the folly of calling a disease incurable because they were unable to discover a cure. Little more than a decade ago diabetes, Addison's disease, acromegaly, syphilitic diseases of the central nervous system, among others, might have been dubbed incurable. How different was the outlook of such patients to-day.

True senile decay first became manifest, as a rule, after the age of 70; it often did not occur till much later. Senile symptoms, often seen in the sixth or seventh decade, should not be designated as old age, when some insidious or obscure disease might be the *causa causans*. Use of the term senile implied the assumption of inevitableness leading to these victims of diseases being placed out of sight in homes for the remainder of their days, rather than regarded as patients requiring medical treatment.

THE CHANGING OUTLOOK

During the past twenty years there had, said Dr. Brander, been evidence of changing sentiment towards chronic diseases. Many voluntary hospitals and clinics, as well as social organisations in different parts of the country, had been actively promoting treatment, research, and public education, especially for malignant diseases, diabetes, and rheumatism. But the great majority of chronically ill still received no organised attention. This was beginning to be appreciated by those responsible for medical education. The medical school of Columbia University recently issued a circular saying:—

"Patients suffering from chronic diseases form the bulk of the physician's private practice, and because of the complexity and long duration of their illnesses, they are among the most difficult whom he is called on to treat. Because of the belief that this aspect of the practice of medicine does not receive the consideration it deserves, special stress will be laid throughout the courses on the diagnosis and treatment of chronic diseases."

Thanks to the Local Government Act, 1929, there was a decided trend towards a general recognition of responsibility by public authorities for the enlightened care and treatment of the chronic sick. In spite of the two Royal Commissions of 1832 and 1909, recommending better classification of inmates of workhouses, the L.C.C. soon recognised that there had been no consistent policy amongst the late twenty-five boards of guardians. The L.C.C. decided at once to abolish the mixed workhouses, with their hotchpotch of unclassified able bodied, aged, infirm, and chronic sick. At the same time, they launched comprehensive schemes for the reconditioning of certain institutions for ultimate use as hospitals. Perhaps the L.C.C.'s greatest contribution to date was the establishment of special units or clinics in the general and special hospitals. For children there were units for congenital defects, orthopaedic troubles, heart disease, rheumatism, diseases of the central nervous system, and congenital syphilis; for patients of all ages units for cancer, urological diseases, encephalitis lethargica, surgical tuberculosis, and chronic arthritis.

Two other units demanded special mention. Realising what could be achieved in the management of diabetes by expert medical treatment, diet regulation, and the whole-hearted coöperation of the patient, special units were set up at certain East End hospitals in whose area there was a high incidence of diabetes. Expert guidance at mental observation wards and psychiatric clinics is found to be of great help in guarding against the lapsing into chronic invalidism of those who are curable in the earlier stages of their disease. Such experts are allocated to the special units attached to certain hospitals. Another important development was the payment of an annual grant by the L.C.C. to the district nursing association for services to the chronic sick at home.

SPECIAL HOSPITAL FACILITIES

Those who suffer from chronic disease have, Dr. Brander went on, the right to expect medical and nursing care such as only the well-equipped modern hospitals can provide. The medical profession and the more enlightened among the public are no longer satisfied with the old attitude. At present local authorities are divided as to whether (1) to reserve hospitals entirely for the acute sick and others for the chronic sick; (2) to have hospitals in which both are accommodated. The L.C.C. favour a combination of acute and chronic pavilions in the same curtilage; when the present reconstruction is complete London will have over 2000 chronic sick beds associated with seven first-class acute general hospitals. One argument in favour of the mixed hospital deserves emphasis. It is desirable that the nurse's training should include care of the chronic sick; their psychology is very different from that of the acutely sick. The nurse who attends such patients month by month has a sounder knowledge of many branches of her profession than her colleagues who have trained in general hospitals. Whatever policy be adopted, accommodation should have regard to the special needs of the chronic sick—e.g., wide doors and corridors to permit the free passage of wheeled chairs, capacious alcoves or closets for their storage. The whole equipment and medical

organisation should be as complete as that for the acute patient. Patients should be classified in accordance with the nature of their disease and their age. Special services such as occupation therapy, physiotherapy, and social services are essential. In short, the modern chronic hospital should be a centre for medical education and research, offering special opportunities for study of the aetiology, treatment, and prevention of chronic diseases.

Dr. Brander concluded with an appeal for the complete coördination between all agencies, public and voluntary, dealing with the chronic sick problem from the hospital, institutional, and domiciliary standpoint. When orderly ideas had been formulated, and systematic planning established, the public would face the necessity for a change of policy. They would come to realise that their responsibility was at least as great for the chronic as for the acute patient, and that poverty was irrelevant. They would find that the present haphazard methods were imposing a tremendous burden of expense on the community. They would take steps to prevent the enormous waste of money on patent medicines and on various healing cults. They would come to regard the prevention of chronic disease as a pressing public health problem, and money expended in solving it as an investment which would ultimately pay large dividends.

REVIEWS AND NOTICES OF BOOKS

Diagnosis and Treatment of Skin Diseases

By J. H. SWARTZ, M.D., Instructor in Dermatology, Harvard Medical School; and MARGARET G. REILLY, R.N., Graduate, Massachusetts General Hospital Training School for Nurses; Supervisor of Skin Diseases, Massachusetts General Hospital. New York: The Macmillan Co.; London: Macmillan and Co., Ltd. 1935. Pp. 316. 15s.

THE collaboration of doctor and nurse in the production of a text-book is something of a novelty, at least in dermatological literature. The outcome of their joint effort will certainly appeal to the practitioner who aspires to something more than a prescription for calamine lotion, or advice to apply ultra-violet rays. Both nursing and ambulatory treatment are described in minute detail, no less than 5½ pages of type being devoted to the treatment and prevention of epidermophytosis alone. There is a long chapter on syphilis. The technique of intravenous injections is illustrated by numerous line drawings and diagrams of the requisite apparatus for use by doctor and nurse. Precise instruction on the care of needles and syringes is supplied, and the public health and social aspects of the disease are well discussed. Some clinical photographs illustrate the text. A chapter on the care of the normal skin is a new departure in a text-book on dermatology; it includes sections on the various types of baths available for cosmetic purposes, on the care of the feet and hands, and on special methods for the use of those afflicted with dry or oily skins. The treatment of hypertrichosis, freckles and wrinkles, and the sclerorrhoic scalp are included in this section, and the authors have even invaded the province of the hairdresser in discussing "permanent" and other methods of waving the hair. It is useful to learn, for instance, that a greasy scalp will probably benefit by "permanent waving," while the disadvantages associated with the dry type of scalp will be aggravated by this desiccating procedure. Here, too, will be found

useful so-called "tonic" prescriptions for use with dark and with light hair, designed to prevent the risk of undesirable modifications of a carefully selected and expensive tint. The section on the care of a baby's skin from the moment of birth will provide information not to be spurned even by the most experienced. There is a most welcome chapter on the exanthemata, while dermatology proper, which occupies the main bulk of the book, receives ample consideration on the regional basis. There are 21 charts or tables pertaining to the differential diagnosis of the commoner dermatoses, with clinical photographs to illustrate their main localisation and characteristic features.

We welcome this original contribution to the teaching manuals.

The Body and its Health

By WINIFRED CULLIS, C.B.E., M.A., D.Sc., LL.D., Sophia Jex-Blake Professor of Physiology, University of London, London (Royal Free Hospital) School of Medicine for Women; and MURIEL BOND, M.Sc., Assistant Lecturer in Physiology at the same school. London: Ivor Nicholson and Watson Ltd. 1935. Pp. 216. 3s. 6d.

Prof. Cullis and Miss Bond believe that the human body is badly treated because its possessors do not bother to find out how to make the best use of all its powers. It is their view that some knowledge of the body and of the laws of hygiene would result in a healthier and happier community, and they have written this book for the purpose of popularising this knowledge among young people. The publisher's jacket states that the book is intended to appeal to boys and girls of school age, but it will probably be found more useful in the hands of the teacher of hygiene than in those of the members of the class. There may be no satisfactory way of avoiding the use of many scientific terms in presenting a subject of this kind, but in some places such terms are

perhaps taken too much for granted and their explanation is deferred rather too long. The illustrations are lavish and clear, but school-children may be mystified by such a legend as that on p. 50: "Diagram showing localisation of function in the cortex of the cerebral hemisphere."

The student is taken through a comprehensive course, beginning with the living body as a whole, and going carefully into the various systems and their functions. The skeleton, muscles, nerves, special senses, circulation, respiration, digestion, kidneys and skin, and the ductless glands are dealt with in turn, and various matters of everyday life, including food in the home, clothing, care of the bowels, and ventilation, are discussed in separate chapters. For practical usefulness special praise may be given to the sections on respiration and ventilation, and to the short chapter on the special senses as a whole. Much helpful advice is given on diet, with a series of tables showing the sources of the various elements required to ensure satisfactory nutrition. The book is well printed and indexed, and is remarkably cheap.

Materia Medica, Pharmacy, Pharmacology and Therapeutics

Twenty-second edition. By WILLIAM HALE-WHITE, K.B.E., M.D. Lond., M.D. Dub., LL.D. Edin., Consulting Physician to Guy's Hospital. Revised by A. H. DOUTHWAITE, M.D., F.R.C.P., Physician to Guy's Hospital; Physician to All Saints' Hospital. London: J. and A. Churchill Ltd. 1935. Pp. 552. 10s. 6d.

If any text-book can be said to have stood the test of time, it is Hale-White's *Materia Medica*. First published in 1892, it has gone through edition after edition, and now, only three years after its predecessor, appears the twenty-second edition. The general plan of the work has not been altered, but Dr. Douthwaite has found it necessary to make considerable alterations and additions to the text. The chapter on the actions and uses of digitalis has been rewritten, additions have been made to the articles on sera, vaccines, vitamins, and nitrites, and the author has tried to simplify the study of the barbiturates by introducing Mutch's table. Non-official and trade preparations have not been neglected, and the section on pharmacy has been revised. The whole production gives a full account of modern pharmacology and therapeutics, and is well up to the standard of previous editions.

Groedel's Röntgendiagnostik in der Inneren Medizin

Fifth edition. By HEINZ LOSSEN. X Ray Director of the Hospital zum Heiligen Geist, Frankfurt a.M. Munich: Lehmann. 1935. Pp. 187-398. With 104 illustrations and 54 plates. M.24.

The second part of this well-known atlas and text-book has been almost completely rewritten and largely reillustrated for this fifth edition. The companion volume dealt chiefly with physics, technique, and organisation; this one in some seven chapters covers the skull, teeth, sinuses, chest, and diaphragm. The standard attained is high, particularly in the chest sections, and each chapter is written by one who can speak with authority. The illustrations are either photographic prints of radiograms or clear diagrams. It is regrettable that here as in many other text-books it is the extreme or the

unusual that is pictured rather than the borderland case, often met with in daily practice, which leads the radiologist to seek help from a text-book. This is particularly true as regards the exceptionally fine reproductions in the dental section. The radiographic technique of each division is simply and adequately described and the discussion of each subject is sufficient. There is no index, nor even a list of chapter headings; presumably these will be published in a later volume of the series.

Elementary Textbook of Anatomy

By HENRY E. CLARK, C.M.G. New edition, revised by JOHN GRAHAM, B.Sc., M.B., Ch.B., F.R.F.P.S., Professor of Anatomy in the Anderson College, Glasgow. London and Glasgow: Blackie and Son Ltd. 1935. Pp. 278. 6s.

THIS little book, for junior students and nurses, appears to be reliable within the necessarily narrow limits in which it is set. It seems to have been revised with care, and the facts it presents are simply and clearly set out. The terminology used is rather out of date in some places, but that is a minor matter, and we expect that the book will fulfil its purpose very well.

St. Bartholomew's Hospital Reports

London: John Murray. 1935. LXVIII. Pp. 351. 21s. (subscribers 15s.).

THIS volume is remarkable for the number and variety of the subjects discussed in its pages, and it serves to show how knowledge may be gained from the study of carefully prepared clinical records. This is true particularly of the papers on pink disease by Dr. C. F. Harris, on fractures of the carpal scaphoid by Mr. J. P. Hosford, on carcinoma of the stomach by Mr. R. W. Raven, and on Raynaud's disease by Prof. Paterson Ross, all of which draw attention to the practical problems of prognosis and treatment. The results of two new methods of treatment are recorded—the X ray treatment of carcinoma of the oesophagus recently modified by Dr. W. M. Levitt, and Dr. R. G. Macfarlane's work on the treatment of hæmophilia by snake venom, which is noticed on another page. In the collection of five articles which constitute a symposium on infections of the urinary tract special attention must be directed to those by Mr. W. Girling Ball and Dr. L. P. Garrod. Mr. Ball has been able to show in a striking series of cases how frequently unilateral infection is associated with some predisposing obstructive lesion in the renal pelvis or ureter; and Dr. Garrod has described a method of estimating the efficiency of urinary antiseptics designed to make it possible to determine which of the substances commonly recommended can in fact sterilise the urine, and the conditions under which they may achieve this object. A paper by Mr. R. C. Elmslie on fibrosis of bone, which is a continuation of his earlier publications on other subjects, and Dr. G. D. Kersley's essay on growth and metabolism, light on some of the more

In addition to a statistical report from the cancer department of the hospital, and some shorter contributions on pathological subjects by Mr. C. K. Vartan (the nature of leucorrhœa), Dr. R. G. Anderson (the plasma phosphatase in jaundice), and Mr. F. d'Abreu (adamantinoma of the jaw), there is an appreciation of the late Mr. F. A. Rose who helped to establish and organise the throat department, and an interesting analysis of the careers of some hundreds of former students prepared by Mr. Ball as dean of the medical college. He has been able to show that the reason why so large a proportion of university students never take a degree is not because they fail to pass the final university examination but because they never enter for it.

THE LANCET

LONDON: SATURDAY, OCTOBER 19, 1935

ARTIFICIAL PNEUMOTHORAX AND AFTER

It has been remarked that the treatment of pulmonary tuberculosis is the treatment of cavities. There are, it is true, certain types of fibrous-walled cavities which occur chiefly in the fibroid phthisis of later life which may persist for a decade or longer without causing any serious symptoms or giving rise to progressive disease. But apart from these examples of exceptional resistance there are few exceptions to the rule that a cavity which fails to close on rest, or which cannot be closed by artificial means, will lead to the death of the patient within a limited period. Nor is this surprising. A cavity is a natural incubator where the tubercle bacillus can breed under ideal conditions and avoid the perils of overcrowding by migration along open routes to fertile territories adjacent or across the carina. It is more surprising that the closure of a tuberculous cavity by the simple apposition of its walls is usually followed by healing and that after a cavity has been closed, for a period of a few months in some cases and a few years in others, re-expansion of the lung does not give rise to any breaking down of tissue recently friable. So long as a cavity remains patent the consumptive's life is in danger. The temperature may be normal, the pulse show no quickening, symptoms may be in abeyance, and the general condition excellent; but if the skiagram still shows evidence of excavation there is no basis for optimism. If tubercle bacilli persist in the sputum, even though X rays reveal no sign of excavation, ulceration must still be assumed and excavation though possibly of minimal extent must be inferred. An appreciation of these facts has led to the early employment of collapse therapy in the treatment of pulmonary cavitation, for the soft-walled cavities of incipient disease as a rule yield readily to artificial pneumothorax.

If pulmonary tuberculosis were always discovered in the stage of early infiltration the difficulties of its treatment would be few, though when the disease is subpleural and the lung membranes are involved simultaneously with the lung parenchymatous adhesions between visceral and parietal pleura may be present almost from the start. But early diagnosis is seldom possible. Incipient disease may give rise to no symptoms, the practitioner may fail to realise the significance of symptoms, or the patient actuated by fear may refuse to report sick. When disease has persisted for more than a few months complete collapse can seldom be secured by means of a pneumothorax. In some cases symphysis of the pleura prevents the entry of air into a pleural space no longer potential. In others a collapse incomplete but

sufficiently effective to close cavities may be attained. In the remainder a measure of collapse is secured, but adhesions, which form most readily over excavated areas, anchor cavity-containing areas to the chest wall. Success may, however, still be attained, for adhesions may stretch under the influence of a carefully controlled pneumothorax. If the diseased and excavated lung is held taut by adherence at apex and base phrenic avulsion may relax tension and, with negligible risk or inconvenience to the patient, lead to a rapid closure of cavities though possibly at the expense of the partial sacrifice of some areas of healthy lung. If these methods fail the pneumothorax is sometimes maintained either from fear of depressing the patient by its discontinuance or because an easy optimism induces a vague hope that things will improve. Such an attitude is at once timid and ineffective. An artificial pneumothorax which is doing no good is probably doing harm. It should either be made effective or abandoned. There is no middle way. If it is abandoned the patient must either be left to die, or be urged to submit to a thoracoplasty—a crude and mutilating proceeding which often fails to achieve its object. In most cases the best means of overcoming the difficulty of the ineffective collapse is to render it effective by internal pneumolysis, a method which enables the patient to avoid the perils and pains of two or three major operations (or, to adopt current euphemism, a major operation performed in two or three stages), and which enables the physician to secure collapse exactly where the collapse is needed and thus to avoid the hazards of phrenic avulsion, the result of which though sometimes excellent can seldom be accurately predicted.

When performing an internal pneumolysis the operator's vision is limited by the very small field determined by his endoscope. He is working in a confined space, the mobility of his instruments is hampered by the costal arches, the adhesions to be severed are often in close proximity to vital structures, and bleeding can only be controlled indirectly by diathermic coagulation. The risks attending work of such a kind might well seem to outweigh the possible benefits of successful adhesion section. But those who are prepared to master the technique need not be deterred from the practice of internal pneumolysis by imagined dangers. Dr. F. G. CHANDLER, who has taken a leading part in demonstrating the method of Jacobaeus in this country, has proved—as MAUREL, GRAVESEN, and others have proved elsewhere—that if a rigid technique be followed, if infinite patience be observed, and meticulous care taken, the risks of internal pneumolysis are small. No one who reads the story of individual cases or who studies the statistics supplied will dispute the author's opinion that the results of internal pneumolysis are highly gratifying. Those who have had the opportunity of either performing endoscopy or attending endoscopic operations at home or abroad will note with interest that Dr. CHANDLER is still inclined to favour a single puncture where this is feasible. In his hands

this method has yielded excellent results in the section even of very thick adhesions. The more usual practice involving two punctures will probably continue to be the method of choice for most workers.¹ The technique adopted is of minor importance. It is, however, of paramount importance that whatever method be used the same care should be exercised to avoid the dangers inherent in any closed method of operating within the thoracic cavity. A recent warning by Mr. TUDOR EDWARDS² is opportune, and the beginner should realise that any damage to the lung will lead to "complications much more serious than the condition for which the operation is undertaken." Until practice has brought experience and confidence he must be prepared to restrict his work to the simpler types of adhesion. But those who by study and discipline have qualified themselves for work of this kind will not regret either the time or the labour spent in acquiring the skill necessary for the successful treatment of disease once inevitably fatal and now frequently curable. There are cases where, as Dr. MAURER³ insists, the section of adhesions may mean for the patient the difference between life and death. Operative endoscopy may not greatly affect public health statistics, but it is of vital importance to individual sufferers.

BOVINE VACCINATION AGAINST TUBERCULOSIS

At the conclusion of the test of Spahlinger bovine vaccine in Northern Ireland, related in these columns a fortnight ago (p. 780), an official of the Ministry of Agriculture in Belfast suggested that the satisfactory nature of the results obtained raised the question of making compulsory use of the vaccine as a means of eradicating tuberculosis from the herds of Northern Ireland. This prospect has indeed been raised, but before it can be realised there are a number of doubts and difficulties about the use of any bovine vaccine which will have to be cleared up. A comparison of the results obtained in this and other investigations shows that the problem of immunisation has been approached in several different ways. Thus, since McFADYEAN's first attempts to induce immunity with old tuberculin, many other substances have been used—e.g., the split products of bacillary substance, bacilli killed by various agents, and living bacilli whether of human, avian, ichthiic, or modified bovine strains. The methods of vaccination have also varied within wide limits. Some investigators have been satisfied with one large vaccinating dose, others have tried a yearly revaccination in the hope of prolonging the period of immunity, whilst almost every possible route has been used for the introduction of the vaccine. The resistance test dose of tubercle bacilli given later to demonstrate the immunity produced has varied equally widely. Some experimenters have used emulsions of tuberculous tissues in

which the number of bacilli cannot have been known with any degree of certainty; others have used cultures of bacilli of known virulence and of carefully estimated dosage; others again have relied on exposure to natural infection on the farm. Even that is not the end of the almost infinite variety in the conditions of trial, for animals have been maintained during the experiments in rigid isolation, or under ordinary farm conditions, or on a free range in the open air. Lastly, not a few of the investigations have been made with numbers of animals too small to be of statistical significance. The reason for this is apparent: the cost of field experiments is of a very different order from that of laboratory experiments with guinea-pigs and rabbits. Among the recent investigations made with significant numbers may be cited the careful researches of WATSON (72 animals) carried out under the aegis of the Canadian Government, in which the immunity conferred varied between two months and four and a half years; and those of BUXTON and GRIFFITH (51 animals) with grants from the Cambridge Institute of Animal Pathology and the Medical Research Council, in which immunity extended from eight months to three years—the latter series being entirely immunised with BCG vaccine, the former with BCG plus a virulent strain. An extensive field experiment was also recorded two years ago by DREYER, VOLLUM, and AMMITZBÖLL, with diaplyte vaccine, in which 281 animals on a heavily infected farm were vaccinated without interference with farm conditions during a period of nine years. In this case 90 per cent. of the cattle on the farm were tuberculous at the beginning of the experiment, and although the immunised animals were allowed to mix freely with the infected stock only 2 of the 281 animals developed clinical tuberculosis.

New factors have been introduced in the Northern Ireland experiment. Various types of vaccine and bacterial product were used, the most important being the "new simplified dead vaccine" of Mr. SPAHLINGER in which the organisms were not killed by any of the ordinary laboratory methods but by exposure in a cool dark place until all the bacilli in the emulsion had died a natural death by the efflux of time—a year or even longer. A high resistance test dose of bacilli was selected—viz., 2.5 mg. of growth administered intravenously. Seven different strains of bovine bacilli were used in the preparation of this test dose, of which three were obtained from milk by direct cultivation, and apparently without previous guinea-pig control to ensure their virulence. The other four strains had been isolated by guinea-pig inoculation. Preliminary tests were made of the combined virulence of the assembled seven strains, but no previous information was available regarding individual virulence prior to the test. The calves used for the experiment had been reared out of doors and were allowed to continue in the open to the end of the experiment. Whilst this experiment impresses by the long period of immunity obtained and its high degree, the number of animals were small—very small indeed to base a plea

¹ Vide Scott Pinchin, A. J., and Morlock, H. V.: *THE LANCET*, 1931, i., 1300.

² *Ibid.*, Oct. 12th, 1935, p. 853.

³ *Irish Jour. Med. Sci.*, September, 1935, p. 537.

for compulsory vaccination upon. It must be regretted by all friendly observers that the calves used for the minor experiments with old vaccine and bacterial products were not all devoted to the major issue of testing the new simplified dead vaccine prepared in 1929, for which purpose only 11 calves out of 32 available (including controls) were used. We have no doubt that before resort to any compulsory scheme of bovine vaccination based on this most suggestive experiment it is essential that standard conditions should be laid down for estimating the value of a bovine vaccine. No doubt the inherent difficulties of the task have been largely responsible for the variation in technique, and a field experiment on an adequate scale is beyond the means of any voluntary research institution. The preparation and standardisation of vaccines on a large scale needs careful control, especially when dealing with those made from modified living organisms, such as BCG, or from bacteria which have been allowed to die by the efflux of time, such as the Spahlinger vaccine—to mention two which have become important of recent years. Indeed, as far as we are aware, no one has yet prepared the Spahlinger vaccine except the originator himself. To these questions must be added the cognate problems of suitable environmental conditions of the animals under test, the duration of the immunity attainable and the most satisfactory way of measuring it. Above all, a team of workers is needed who will adequately represent the different branches of bacteriology, immunology, and veterinary science. The experiment in North Ireland justifies a survey of this kind.

HÆMOSTASIS IN HÆMOPHILIA

"The sight . . . of a patient slowly becoming exsanguine from a trivial injury, capable, perhaps, of being securely enveloped in bandages, must leave a lasting impression on the observer."

THE studied moderation of this sentence from BULLOCK and FILDES's monograph on "Hæmophilia" hardly conveys the sensation of therapeutic bankruptcy which assails the clinician faced with a case of hæmophilic hæmorrhage. This very helplessness has, in the past, encouraged the use of such heroic measures as hot irons, tar, and strong acids, which were not only valueless but prejudicial, in themselves, to the patient's existence. About a year ago Dr. R. G. MACFARLANE and Dr. BURGESS BARNETT published in *THE LANCET*¹ their discovery of a new hæmostatic of much promise in the treatment of external hæmophilic hæmorrhage. This agent, it will be remembered, was a solution of the venom of Russell's viper,² an Indian snake. MACFARLANE has now reviewed the control of accessible hæmorrhage in hæmophilias with special reference to the use of this venom.³

The hæmorrhagic tendency in hæmophilia seems to be due solely to a disturbance in the coagulative mechanism of the blood. The fundamental fault upon which the prolonged coagulation time depends is not yet clear, but the hypothesis which is perhaps most favoured at the present time is that all the phases of coagulation are slowed owing to an abnormal stability of the plasma colloids. Our ignorance of the pathogeny of hæmophilia makes it impossible to attempt to correct the underlying abnormality in a rational manner. The only measure which will diminish coagulation time over a considerable period is transfusion of blood. In the absence of effective general measures, the local treatment of hæmorrhage assumes great importance, and, unsatisfactory though it may be, the only method of dealing with a hæmophilic patient at the present time is the scrupulous avoidance of traumata and the efficient and prompt treatment of hæmorrhages, when they are accessible, by local means and by blood transfusion. It is particularly this last aspect which is discussed by MACFARLANE in his latest paper. Internal hæmorrhage still remains almost certainly fatal. From the nine cases which he reviews he is able to draw certain conclusions and to suggest a tentative system of treatment. The first two were treated before Russell's viper venom was available, but in the remaining seven it was employed successfully as a hæmostatic, supplemented in two cases by blood transfusion. The venom has the power, *in vitro*, of causing hæmophilic blood to form a tough elastic clot. One experiment may be quoted to show its extraordinary potency: a specimen of hæmophilic blood which took 35 minutes to clot spontaneously, clotted in 17 seconds on the addition of one-tenth its volume of 1 : 10,000 Russell's viper venom solution. Fortunately the coagulant power of the venom does not diminish in direct proportion to the dilution and a coagulant effect could still be demonstrated after a dilution of 1 : 10¹⁸; thus in high dilution an extremely potent coagulant action is retained while other possible toxic effects of venom are absent. The sterility of solutions was ensured by passage through a Berkefeld filter. This interesting series of cases represent the first clinical trials of a remarkable coagulant. From their consideration MACFARLANE is led to condemn certain therapeutic measures in common use. Pressure upon injured tissues should, he holds, never be maintained for more than a short time. Its value consists merely in decreasing the blood flow a sufficient time for the hæmostatic to produce a firm clot. Pressure applied for longer is almost certain to lead to necrosis of already devitalised tissue. This is well demonstrated in his Case 9, where a tightly fitting dental plate led to necrosis and subsequent infection of a tooth socket; the condition did not start to improve until all local applications were discontinued. Experience with other hæmostatics has shown that Russell's viper venom is the most effective one available, and that if it fails others are not likely to succeed. Meddling with the wound is strongly deprecated and irritants should never

¹ THE LANCET, 1934, II., 985.

² We understand that Russell's viper venom is not yet on the market, but can be obtained for use in dental or surgical clinics, or by a doctor or dentist actually requiring it for the treatment of bleeding in a hæmophilic, on application to the director of the Wellcome Physiological Research Laboratories, Beckenham, Kent.

³ St. Bartholomew's Hospital Reports, 1935, LVIII., 229.

be used. Adrenaline may have a temporary value in decreasing the local blood-supply, but if applied repeatedly has the same dangers as prolonged pressure. The cautery "is worse than useless in cases of hæmophilia and should never be employed." Sutures should not be used unless it is certain that they will not cut out; suturing the skin edges over wounds in which the bleeding is not completely controlled is regarded as certain to lead to extensive hæmatoma formation. An illustration of this danger is provided by Case 8 in this series, where a cut on the dorsum of the right hand was sutured on two occasions; the day following the second suture the hand was so swollen with effused blood as to be "almost spherical." Hæmorrhage was eventually controlled by removal of all sutures, the wound being lightly packed with gauze soaked in Russell's viper venom.

The advice given for the treatment of accessible hæmorrhage in cases of hæmophilia is as follows:—

"The wound should be very carefully and gently cleaned out, and useless clots removed. A dressing soaked in Russell's viper venom should be applied, or lightly plugged into the cavity. Some means should be adopted to keep the dressing firmly in place without movement. In the mouth a well-fitting plate should be employed, a loose plate is

useless as its movements dislodge the clots that form. This form of treatment can usually be relied upon to arrest or at any rate greatly diminish the bleeding. If it still continues the application may be repeated, using a hot dressing at 50° C. If this fails, the best that can be done in the way of light packing with gauze soaked in adrenaline and snake venom should be carried out. Further hæmorrhage should be disregarded and no drastic steps taken to arrest it. The wound should be left alone and the patient allowed to bleed. He should be watched carefully and at the first indication a full transfusion of normal blood given, repeated, if necessary, until the bleeding stops. This will occur when healing takes place, and repeated interference with the wound will only delay matters. It cannot be too strongly emphasised that any other measures than those suggested are almost certain to be useless and to delay healing. The hæmophilic patient usually loses his blood slowly, and even when bleeding is untreated, it will probably be found that a transfusion is only necessary every other day. Naturally, the patient will be alarmed at the continued hæmorrhage, and his reassurance by the explanation of the position is a very necessary part of the treatment."

The case reports in Dr. MACFARLANE'S paper bear testimony to the success which accompanies this simple and rational therapeutic scheme, and there seems to be no doubt that in Russell's viper venom we have the most, if not the only, effective local agent for the arrest of hæmorrhage in hæmophilic patients.

ANNOTATIONS

A DANGEROUS DRUG

THE increasing importance and danger of agranulocytosis is shown by the fact that it is held responsible for 1500 deaths in the United States alone in the three-year period ended in 1934.¹ Since the disease was first described many efforts have been made to determine its cause. There is at present no satisfactory evidence to support a dietary deficiency as an ætiological factor though this possibility has been investigated. Since the neutropenia in many cases has been shown to precede the onset of septic conditions, it is presumably the cause and not the result of bacterial invasion of the tissues. The frequent occurrence of attacks at the menstrual period has suggested a possible but entirely hypothetical hormonal dysfunction. The evidence incriminating a certain group of drugs is, however, extremely strong. That such drugs may not be involved in all cases is clear from the work of Jackson,² but as Kracke and Parker point out,¹ they have certainly played an essential part in some. These workers conclude that of the drugs incriminated by various observers amidopyrin (Pyramidon), dinitrophenol, and possibly other closely related preparations must certainly be considered ætiological agents. They have collected 172 cases from all over the world in which the illness has definitely followed the use of these substances. In some instances successive attacks have followed further administration of the same drug, and a somewhat similar picture has been induced in animals by similar means. The disease is certainly most prevalent in that class of people—notably doctors, nurses, and their families—who are the largest users of these drugs, and its first appearance

seems to be closely related to the time at which the amidopyrin-containing preparations came into use. Amidopyrin is a constituent not only of drugs usually ordered by the physician, but also of medicines or tonics advertised to the man in the street. In this country it is probably prescribed most often in the form of Allonal, which is increasingly used both as hypnotic and analgesic. It also forms part of the preparations Amytal compound, Cibalgin, Compral, Dismenol, and Prokliman. By those who admit the possibility of danger the argument is put forward that the amounts taken in these compounds are small and the risk in practice negligible. But the evidence now marshalled by Kracke and Parker makes it clear, in our opinion, that amidopyrin in any form should no longer be used when other equally effective drugs are available and that it should be ordered only by a non-repeatable prescription. Too often patients are told to take a tablet when they feel like it, for the relief of pain or insomnia; whereas, for the present, it seems best to regard amidopyrin, and preparations containing it, as dangerous drugs.

AVIATION MEDICINE

THE careful medical selection of flying personnel, both for the Royal Air Force and professional civil flying, is one of particular importance to this country, especially at the present time when the rapid expansion of flying has resulted in a greatly increased demand for pilots in both the Service and civil branches. The necessity for a thorough and careful medical examination is now generally accepted, but in the early days of the late war this was by no means so, and the figures, quoted in the September number of the *Military Surgeon*, for British casualties among fliers in the first year of the war are eloquent proof of the need for such examination. The quoted figures show that, out of every 100 fliers killed, 2

¹ Kracke, R. R., and Parker, F.: *Jour. Amer. Med. Assoc.*, Sept. 21st, 1935, p. 960.

² Jackson, H., Jr.: *Amer. Jour. Med. Sci.*, 1931, clxxxviii., 482.

met their death at the hands of the enemy, 8 from some defect of their machines, and 90 through an individual deficiency such as physical unfitness, recklessness, or carelessness; 60 of them were attributed to physical defect. As a result of a special service being inaugurated for the "care of the flier," these fatalities due to physical defects were reduced from 60 per cent. to 20 per cent. at the end of the second year, and at the close of the third year to 12 per cent. In the United States the first standards laid down in 1914 were so high that no candidate was found capable of passing the tests. Brigadier-General W. H. Wilmer gives an interesting account of the gradual development of the present standards and of the various methods of testing the probable capabilities of the flier for high altitude flying. The routine use of oxygen at altitude has lessened the importance of tests in the decompression chamber as a regular procedure, and in this country they are no longer employed as part of the regular examination of aviation candidates. The decompression chamber is still used, however, for special research such as that entailed in the production of new oxygen masks and work of this nature.

Although the different nations employ varying methods in the medical selection of their flying personnel, the methods current in this country appear to be at least as thorough as those elsewhere; and the medical branch of the Royal Air Force, which examines both Service and civil pilots at the Central Medical Establishment in London, is fully alive to the importance of developing this relatively new but none the less important branch of medicine.

PULMONARY OSTEO-ARTHROPATHY

THE occasional association of bony changes with chronic pulmonary disease has long been familiar, but the causative link has been hard to trace. Much experiment in the department of surgery at the University of Chicago¹ has once more failed to reveal it, but the study of two well-marked cases of the disease has led to conclusions worth notice. It is recognised that any advanced pulmonary change may give rise to osteo-arthropathy if long enough continued, and chronic valvular disease may also cause it, when associated with passive venous congestion. The three commonest causes according to the Comperes and Adams are bronchiectasis, empyema, and tuberculosis with cavity formation; in their own two patients the primary conditions were blastomycosis of the chest wall (with secondary infection and empyema) and carcinoma of the lung (with involvement of the bronchi and large blood-vessels but no thoracic suppuration). Cases like the second of these are evidence against the idea that the changes in the bones are due to absorption of bacterial toxins, and so is the finding that periosteal new-bone formation sometimes occurs in people free from intra-thoracic disease, but living at high altitudes. The only factors common to the two cases studied at Chicago were dyspnoea, cyanosis, and a change in the hydrogen-ion concentration of the blood to the alkaline side. These signs, it is thought, like the changes at high altitudes, may all be explained as due to a decrease in the oxygen content of the serum, possibly with an increase in metabolic waste products. Besides the most constant and striking alterations, which are seen in the shafts of the long bones, there are other tissue changes, giving rise to the familiar clubbing of the fingers, and to painful joint conditions.

¹Comperes, E. L., Adams, W. E., and Comperes, C. L.: *Surg., Gyn., and Obst.*, September, 1935, p. 512.

characterised by synovial swelling, and later by erosion of cartilage from the articular surfaces. In the bones the periosteum is raised by successive layers of cancellous bone, seen at first in radiograms as laminae. The bone directly underlying the periosteum is denser and forms a sort of secondary cortex, and even in the later stages, when the distinct lamination has disappeared, the new bone does not fuse with the underlying shaft, but surrounds it.

The investigators' failure to reproduce the typical changes in dogs may, they think, be due to the unusual ability of these animals to compensate for loss of aerating tissue.

HODGKIN'S DISEASE

ALTHOUGH lymphadenoma, or as it is generally termed abroad lymphogranuloma, is known to have a wide distribution both in Europe and America, we have still much to learn concerning its incidence in the world generally, and especially on the various races of man. The clinical features of the disease and its characteristic morbid anatomy and histology are now thoroughly established. No disease, however, can be considered to be defined with satisfaction until its aetiology has been solved, and attempts to isolate a causal agent from cases of lymphadenoma have been handicapped by the circumstance that the disease does not appear to exist naturally in the animal kingdom, and in spite of many endeavours all efforts to reproduce it in animals experimentally have failed. Nevertheless, a certain amount of progress in this direction seems to have been made. The latest organised attempt to solve the problem of lymphadenoma, the Rose Research, was carried out by a combined effort at St. Bartholomew's Hospital between 1928 and 1932. Here the possible agency of various micro-organisms known to be capable of producing granuloma, such as tubercle bacilli, spirochaetes, and pathogenic fungi, was excluded. The only positive evidence found was the presence in lymphadenoma glands (in large numbers and apparently in pure culture) of minute "elementary bodies" similar in size, appearance, and staining properties to those found in vaccinia and certain other known virus diseases. Thanks to the work of E. Paschen in Germany, of J. Craigie in Canada, and especially of J. C. G. Ledingham in this country, it is now generally admitted that these elementary bodies are the actual causative micro-organisms in vaccinia. The presence in lymphadenoma glands of similar minute bodies, called by A. C. Coles "virus bodies," is thus highly suggestive.

During the course of the Rose Research it was also noticed that a suspension of the affected lymphatic glands of patients suffering from lymphadenoma, when injected cerebrally into rabbits, generates, after an incubation period of one or more days, a peculiar encephalitic syndrome characterised by loss of weight, rigidity, incoördination, and ataxia. As similarly prepared suspensions of lymphatic glands from patients suffering from conditions other than lymphadenoma had no such action, the intracerebral injection of the rabbit formed a biological test that promised to afford valuable confirmatory evidence in glands removed for biopsy in patients with suspected lymphadenoma and especially in cases where the histological appearance is atypical. During the three years that have elapsed since the Rose research report was published¹ confirmatory evidence of the value of this biological test in question has been

¹The Rose Research Report, London, 1932.

published from Edinburgh,² Utrecht,³ Belfast,⁴ and Treviso.⁵ We learn moreover that up to March, 1934, at St. Bartholomew's Hospital glands from 102 patients in all had been submitted to the biological test on the rabbit's brain: 35 of them were from cases of lymphadenoma and 30 of these gave a positive result. The remaining 67 glands, from patients suffering from conditions definitely not lymphadenomatous, all gave negative results.

The exact nature of the agent or agents responsible for this syndrome in the rabbit has not yet been established. U. Friedemann⁶ has drawn attention to the fact that suspensions of normal human bone-marrow and occasionally of spleen and leucocytes of human origin can provoke similar symptoms in the rabbit by cerebral injection. This was confirmed a few months ago by Ian Mackenzie and C. E. van Rooyen⁷ who brought forward evidence to show that the agent concerned differs from Jochmann's proteolytic enzyme to which Friedemann had called attention in this connexion. The actual cause of this encephalitic syndrome is, therefore, at present unknown. Bortolozzi⁸ found in the rabbits succumbing to an injection of lymphadenoma gland substance histological appearances that he interprets as pointing to a generalised infection with some unknown agent, possibly a virus.

In view of all this work the paper published by E. C. Smith on p. 874 of our present issue is of considerable interest. He furnishes evidence that lymphadenoma exists among the indigenous population of Nigeria, and that glands from these cases not only show the characteristic histological changes of lymphadenoma, but also give a positive result in the biological test on the rabbit. He found that the cerebral injection of monkeys failed, as had also been found by the Rose researchers. Incidentally, Dr. Smith's further experiments with cultures of a diphtheroid bacillus isolated from lymphadenoma gland also provide further evidence of the comparative innocence of this organism which at one time was considered by some to have aetiological significance.

PERSPECTIVE IN MEDICINE

"NATURE meant him to be a healer, for he brightens up a sick room." This quotation from Oliver Wendell Holmes was used effectively by Dr. G. F. Still in his inaugural address to the students of King's College Hospital on Oct. 10th. His practical advice to supplement a "serene and cheerful countenance" with warm hands is likely to be appreciated by the future patients even of those among his audience who may be ungrateful enough to forget, in the course of time, the source of their good habits. Dr. Still's lecture was mainly concerned with the value of a proper perspective in diagnosis, prognosis, and treatment. The Utopian text-book, he said, would describe symptoms in such exact perspective that each disease could be recognised at once by the particular prominence of one symptom, the intermediate position of another, and so forth. But in practice observation and experience were of more value than text-book knowledge, especially if a fashionable idea is not

allowed to obsess the mind of the observer. For example, many cases of vomiting are due to causes other than acidosis; a daily slight rise of temperature may be a sequel to a common cold rather than a sign of tubercle; and wasting may be due to some failure of digestion dependent on faulty diet or defective teeth. In prognosis especially the right perspective is important; and the story of the rapid and complete recovery of a child showing what seemed unmistakable symptoms of tuberculous meningitis gave point to the welcome assurance that increasing years bring to a physician a more rather than a less hopeful outlook. Finally, in treatment proper perspective would ensure the adaptation of curative measures to the needs of the individual patient rather than the attempt to adapt the patient to the desired treatment. The account of the little girl in the last distressed stage of heart disease, exhausting her remaining strength by struggles with the resident medical officer who insisted on giving her brandy, provided a vivid picture of the evils of routine therapy. Other examples offered were the indiscriminate prescriptions for normal children of roughage in diet, glucose, and preparations containing vitamins. In dietetics above all, said Dr. Still, theory had to be constantly checked by experience and observation.

BRITISH AMBULANCE FOR ABYSSINIA

A FEW weeks ago Mr. J. M. Melly described in our columns (Sept. 14th, p. 632) the organisation of an ambulance service for Ethiopia in the event of war with Italy. This British Ambulance Service in Ethiopia has now been officially recognised by both the British and Ethiopian Governments under Articles 10 and 11 of the Geneva Convention. The advance officers, sent some weeks ago to Addis Ababa, Berbera (in British Somaliland), and Nairobi, have cabled that they have carried out their instructions successfully. Dr. T. A. Lambie, in Addis Ababa, has obtained the necessary permits for the personnel and transport of the unit to enter Ethiopia, either by the railway from Jibuti, if it is still functioning, or through British Somaliland; or, should the advancing Italians have rendered that route impracticable, from Nairobi, crossing the frontier at Moyale. He has been assured of the full coöperation of the Ethiopian Government in providing as much lorry and mule transport as possible, and the newly formed Ethiopian Women's Work Association has offered its services for the renewal of supplies of bandages and dressings. Captain J. Purves has reconnoitred the route of entry through British Somaliland to Harar and selected a suitable site for the field hospital in its neighbourhood. He now awaits the arrival of the unit at Berbera. Col. J. M. Llewellyn, in Nairobi, has reported on the alternative route of entry via Moyale on the Kenya frontier should the advancing Italians cut the Berbera-Jijiga-Harar line before the arrival of the unit. With the coöperation of I.E. the Governor and the medical missions in Kenya and Uganda, he is recruiting trained native medical personnel, and reports that 40 such native dressers and 3 Indian sub-assistant surgeons are available.

Meanwhile arrangements in London have proceeded as far as possible until the necessary funds are forthcoming. Applications from a number of medical men have been received but no selection of the seven medical officers required has yet been made, and applications are still being invited. An adequate salary, according to qualifications, is offered; young unmarried men, with some surgical experience, will

⁷ Mackenzie, I., and van Rooyen, C. E.: *Brit. Med. Jour.*, 1935, I., 406.

be given preference. The unit when complete will consist of one field hospital and one casualty clearing station, with 7 medical officers, 2 administrative officers, and the necessary transport officers, trained dressers, transport, and equipment. The money required to send the unit out and maintain it for the first three months in the field is £35,000. The unit will be able to start within two weeks of this sum being forthcoming. An urgent message from the Emperor of Ethiopia just received at the London headquarters of the unit states that the Northern Army is without medical aid and urges that an ambulance unit should be sent to that front without delay. The address of the British Ambulance Service in Ethiopia is 33, Alfred-place, London, S.W.7.

At the same time the Save the Children Fund (20, Gordon-square, W.C.1) is organising relief for Abyssinian refugees to the neighbouring territories of British Somaliland and Kenya. In view of the primitive conditions of the country it is felt that aid must be given to adults if children are to be efficiently helped.

THE PRICKLY PSYCHOLOGIST

THE various schools of psychology are apt to lay emphasis on their differences rather than their concord. In his inaugural address last week as chairman of the Medical Society of Individual Psychology, Dr. C. M. Bevan-Brown spoke regretfully of this tendency towards competition and antipathy and of its effect on the application of psychological medicine. Practitioners often say "when you agree among yourselves we will attend to you, but not before"; and Dr. Bevan-Brown thinks they are largely justified. But he does not agree with the statement, so frequently made, that the schools are irreconcilable and coördination hopeless; a common basis is discoverable if truly sought. It is unjustifiable to assume that any one school is complete or exhaustive and that correlation cannot therefore be expected; indeed, each school contains contributions to the whole problem not possessed by the others, and therefore complementation should be considered as well as correlation. In exhorting his society to give due weight to all views and to abhor sectarianism and bigotry, Dr. Bevan-Brown pointed out that so far as therapeutics is concerned it is fallacious to argue in terms of the various psychopathological theories only. The personality of the physician probably plays a much more important part than his particular theories, and the cures he obtains are often independent of his opinions.

SPECTRA OF VITAMINS AND HORMONES

THE application of spectrophotometric technique to the identification and measurement of organic substances which occur in nature only in very small quantities has helped enormously to advance our more exact knowledge of the vitamins. Association of a definite absorption band with a given substance makes it possible rapidly to follow up the most active fraction in a process of concentration and even to make quantitative estimations of the amount of the substance present. Quantitative estimation of vitamin A by measurement of its absorption in the ultra-violet at 328 mμ has become a matter of practical politics although there are many limitations and pitfalls in the application of the method. All this information is set out conveniently by Mr. R. A. Morton, D.Sc., in a little book recently published.¹

The further application of the method to the spectroscopic estimation of that part of the vitamin-A activity of a material which is due to the presence of the provitamin, carotene, is also described, the absorption in the visible part of the spectrum being here used. A valuable table gives the different absorption maxima of various carotenes and xanthophylls and derivatives of them, together with the comparative biological efficiency, if any, where known. Vitamins B₁, B₂, C, D, and E are also dealt with, although the existing information about them is less complete. The section on the hormones is less informative, since very little work has yet been done with them in this field, though the desirability of applying spectroscopic technique to their estimation is self-evident. The possibilities with respect to the sex hormones, for instance, are very great, but the technical difficulties are substantial, since these hormones are for the most part obtained from very large quantities of urine in which their presence in small amount tends to be masked by that of many other substances. Those proposing to pursue the study either of hormones or of vitamins from this angle will find here invaluable material collected from the scattered literature.

HOSPITAL SERVICES UNDER THE LOCAL GOVERNMENT ACT, 1929

THE Local Government Act of 1929 profoundly influenced hospital development by two instruments. The power of "appropriating" former poor-law hospitals was conferred on public health authorities; the power of providing hospitals for the sick, conferred on municipal authorities by the Public Health Act of 1875, was extended to county councils, including the L.C.C. More is involved in appropriation than mere transference from the Poor Law as is shown in Dr. MacNalty's first report as C.M.O. of the Ministry of Health, of which a brief review is given on p. 913. An appropriated hospital becomes an integral part of the public health service under the supervision of the medical officer of health and, while continuing to provide for the destitute sick, may be developed for wider requirements and may be coördinated with and assist the development of the specialist services of the authority as maternity and child welfare, tuberculosis, and venereal disease. Such development leads to an improved standard of construction and equipment and medical staffing. Coöperation with voluntary hospitals is also facilitated. Further, the enlargement of their sphere from that of individual boards of guardians to a wider authority may bring many hospitals into one coördinated scheme, allowing better distribution and classification of patients and economy of services, as is especially seen in the taking over by the L.C.C. of the functions of 25 boards of guardians and of the Metropolitan Asylums Board. It will thus be seen that the possibilities of organisation and development under the new system are very considerable. Thus in London by new construction and reconditioning 1823 additional beds have been provided since April, 1930, and further improvements are shown by "the provision of 11 new operating theatres, six new X ray departments, five new massage departments and three new dispensaries, in addition to the improvement or enlargement of existing provision under these heads at other hospitals." Better classification may also lead to bettering the lot of the chronic sick whose cause is so persuasively championed in Dr. Brander's presidential address to the Hunterian Society reported on p. 887.

Less detailed information is given in the reports

¹ The Application of Absorption Spectra to the Study of Vitamins and Hormones. By R. A. Morton, D.Sc., Ph.D., F.I.C., Department of Chemistry, the University of Liverpool. London: Adam Hilger Ltd. 1935. Pp. 70. 10s.

of the Ministry of Health and of its chief medical officer regarding development outside London, but sufficient to show that it has also been considerable. Thus appropriation for general hospital purposes has been effected by 30 borough and two county councils, representing a total on April 1st, 1935, of 24,140 beds. In addition, there is appropriation for special purposes, such as children's hospitals, fever hospitals, tuberculosis hospitals, epileptic homes, and mental deficiency institutions. Schemes for alterations and additions to existing accommodation are being carried out or are in preparation by a large number of authorities. The two official reports may be supplemented by reference to some annual reports of medical officers for 1934. Thus Liverpool shows an extensive programme of reconstruction, an increase in admissions over five years of 25 per cent., and a marked increase in the use of special facilities as X rays and pathological examinations. In Manchester, where the municipal hospitals provide three and a half times as much accommodation for the sick as do the voluntary hospitals, it has been found necessary to appoint an assistant medical officer of health in charge of the administration of hospital and municipal services; during recent months there has been reconstruction of the consultant services and the setting up of a Joint Hospital Board for the city. The report for Southampton indicates extension of the medical staff as well as improved equipment and the provision of a maternity unit. At Portsmouth municipal hospital there has been an increase in admissions of 20 per cent. in one year. Essex proposes to erect two hospitals of 500 beds, a hospital of 800 beds for chronic and infirm cases, and two convalescent hospitals of 100 beds. Surrey has approved proposals for the erection of a hospital of some 850 beds. Durham also proposes the erection of a central hospital. These are only illustrations of what is taking place throughout the country. It is gratifying evidence how effective has been the stimulus to hospital development of the Local Government Act.

SIR JOHN M'LENNAN, F.R.S.

THE sudden death last week of John Cunningham M'Lennan, D.Sc., F.R.S., whose name appeared in the last Birthday Honours list, removes a prominent figure in the scientific world, for if not a pioneer, M'Lennan did work characteristic of a man possessed of keen scientific acumen and great executive power. A fellow student with Ernest Rutherford under J. J. Thomson in the Cambridge Cavendish laboratory, M'Lennan spent most of his life in Canada, where he had been born and educated, and turned a small and badly equipped laboratory into one of the finest physics departments in the world, which remains a monument to his driving power and virility as the M'Lennan Institute at Toronto. In these years his most notable public achievement was the production of helium on a scale big enough to make it available for aircraft. But his main scientific work was in radio-activity, and while he did not discover the extraordinary electrical conductivity of metals at low temperatures, he brought it into the field of common knowledge. It should be recalled that nearly 30 years ago M'Lennan showed that what is known as spontaneous ionisation is largely due to the radio-activity of the earth's surface. In the field of optics it was M'Lennan that discovered the origin of the green line in the spectrum of the aurora, which had long puzzled physicists. In 1932, on retiring from the chair of physics at Toronto, M'Lennan

found in this country an outlet for his energy in the treatment of cancer by means of radium. It was he who induced the Union Minière of Brussels to loan large quantities of their stock radium for research, and he was instrumental in organising a clinical unit at the Radium Institute with representatives of the Medical Research Council and other departments. This radium beam therapy research afforded scope for his energies. He possessed the judgment to select the best policies to follow, the best methods to employ, and to sift the good ideas from the bad. He was himself still fertile in new ideas, and the design of a new radium unit with pneumatic transference of the radium embodies many of them. The high density tungsten alloy used in its construction was produced at M'Lennan's instruction. One of his aims was for a joint experiment at the Radium Institute and the Cancer Hospital with three 5-gramme units. This extension of work will take place in the next few weeks, and it is sad that M'Lennan did not live to see the fulfilment of the plans for which he had worked.

" ENSOL "

THE preliminary note¹ in which Dr. H. C. Connell, of Kingston, Ontario, describes his treatment of cancer does not justify the optimistic reports telegraphed to this country. The remedy he uses is a solution containing enzymes believed to be specific for malignant cells. It is prepared by placing human cancer tissue in tubes containing 0.85 per cent. saline solution and inoculating these tubes with a culture of *Bacillus histolyticus*. After 4-6 days' incubation the tissue has been digested by the enzymes secreted by the bacillus, and it is supposed that these enzymes will now prove specifically destructive to malignant cells. The contents of the tubes are filtered through a Berkefeld candle, and the resulting sterile fluid, known as Ensol, is injected intravenously or into muscles. Unfortunately Dr. Connell presents no evidence that the solution contains substances specifically destructive to cancer cells in vitro, and though experiments, in vivo, on mice with transplanted tumours are said to bear out his expectations, the director of the Imperial Cancer Research Fund in our correspondence columns this week reports that similar tests in this country have proved consistently negative. The clinical evidence is based on 30 cases, all of them inoperable, and only the first two patients showed striking improvement. In both these cases pain disappeared, the general condition improved, and the tumour masses regressed; but the period of observation since the beginning of treatment was at the time of writing only four months. In the other 28 cases there is little evidence of more than an easing or controlling of pain with a gain in weight following the treatment.

Dr. Connell has elsewhere committed himself to the statement of his conviction that this work when completed will solve the cancer problem, and we do not think this hopefulness justified by the published data. It appears that the account he gives of the preparation of ensol solution is not detailed enough to enable other competent bacteriologists to supply clinicians with an active product; for he adds that "steps have been taken to prevent the exploitation of the public and the profession by unauthorised interests" and that "no supply of this solution will be made available until its value has been definitely proved." One may well ask why, under these circumstances, the paper was published.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LXXXIII.—PROGNOSIS OF NON-MALIGNANT DISEASES OF THE BREAST

Acute Affections

ACUTE affections of the breast tissue during lactation may, if vigorous treatment is adopted early, subside without suppuration. Should suppuration occur, convalescence is shortened and the total demand upon the patient's strength lessened if surgical treatment is delayed until a definite abscess can be localised. Even if the patient be gravely ill and more than one operation is required, unless there are constitutional complications present, such as renal disease or active phthisis, recovery after a shorter or longer convalescence is the rule.

Acute mastitis also occurs in non-lactating breasts. In these cases one segment only of the breast is, as a rule, affected, and suppuration does not occur. Complete resolution follows simple local treatment in a week or two. Relapses are not uncommon.

There is no evidence that carcinoma occurs with any special frequency in breasts that have previously been the site of acute inflammatory disease.

Chronic Affections

NEOPLASMS

1. *A fibro-adenoma*, the commonest simple tumour of the breast, does not become malignant. Cure of this condition follows local removal. The appearance later of a second similar tumour in the immediate neighbourhood of the first is the result of the growth of a second adenoma so small at the time of the operation as to have passed unnoticed. Cases of multiple fibro-adenomata are common. After many years a small fibro-adenoma may grow rapidly, and especially if this occurs during pregnancy the tumour may attain a great size in a few months. None the less, it remains a simple tumour although now given the more descriptive name of cyst-adenoma. If removed from the breast entire—its lobulated nature may render this a little difficult—or if eradicated by simple mastectomy, cure invariably results.

2. *Duct-papilloma*.—This affection of the breast is unique in being the only one primarily innocent which in time always becomes malignant. Prognosis depends, therefore, upon its recognition before this change has occurred, in which case local excision or simple mastectomy is curative. Unfortunately, in its early stages a duct-papilloma may be symptomless. If, however, either a watery discharge from the nipple with or without an occasional blood stain be present, or puncture of a cyst reveals the presence within it of blood-stained fluid, surgical removal of the affected breast without delay must be advised. If careful histological examination of the suspicious area reveals no penetration of the basement membrane by epithelial elements the prognosis is good.

SPECIFIC INFECTIONS

Tuberculosis.—This rare chronic affection of the breast may occur in a superficial form in or just under the skin, or more deeply as a granulomatous lesion of the breast tissue. Provided that the patient is not suffering from advanced tuberculosis elsewhere—e.g., in the lungs or kidneys—or that the breast is not affected by direct spread of the disease from rib or mediastinum, cure follows simple removal of the affected organ. If from delay in diagnosis or reluctance to adopt this radical line of treatment minor measures

are adopted, the disease may run a prolonged course with frequent relapses but with no appreciable risk of generalisation.

Gummata of the breast, if diagnosed, respond readily to antisyphilitic measures. A mistake in diagnosis will almost certainly result in operative removal of the organ with, of course, local cure.

Actinomycosis, the rarest of the three granulomata, has a grave prognosis, if, as is often the case, it is accompanied by an internal manifestation of the disease, or is due to continuous spread from the neck.

"*Chronic mastitis*."—This term is still used to describe the common clinical condition in which either a segment or the whole gland feels firmer than normal, with a coarse granular surface, but no lump palpable with the flat of the hand. Lenthal Cheatle prefers the name *mazoplasia* as avoiding any suggestion that inflammation is a factor in its production. His view, based upon prolonged study of the histo-pathology of sections of whole breasts, that the condition by whatever name it is called is never a pre-cancerous one, is borne out by clinical experience and is now generally accepted. The true frequency of the condition is only established by careful routine examination of the breasts of all female patients over middle age, rather than by concentration on those patients who complain of breast pain or a lump in whom examination leads to this diagnosis. It has recently been suggested, as the result of such routine examination in a large number of women, that the clinical condition is so frequent as to be almost physiological, complaint only being made of it if the induration is accidentally discovered or if, for some unexplained reason, pain is associated with it. In any case, evidence is accumulating which tends to absolve this clinical condition from any causal connexion with carcinoma. The removal of breasts, the site of "chronic mastitis," is not demanded therefore as a precautionary measure to avoid the danger of cancer.

As has been stated, many cases remain untreated because no complaint is made. When complaint has been made either of induration or pain or both, simple treatment by well-applied firm pressure, maintained at first by night as well as by day, will give lasting relief in a high proportion of cases. An alternative non-operative measure where this line of treatment fails is a course of X ray treatment, which also results in local resolution and disappearance of pain in most cases. Sometimes pain of a neuralgic character persists in spite of such treatment, but often such cases present other features which suggest that cancer-phobia or an unhappy mental state due to some other cause is a major factor in the persistence of the complaint. In such cases removal of the breast certainly cures the local condition, but may be followed after a longer or shorter interval by complaint of the opposite breast, leading to removal of this organ also.

"*Chronic cystic mastitis*."—To this condition in which with or without an area of breast induration and nodularity one or more cysts large enough to form definite tumours are met with. Cheatle gives the name *cystophorous hyperplasia*. The nature of the lump or lumps present is determined by careful examination with the fingers, or an exploratory puncture may evacuate the characteristic dirty opaque fluid contained in these simple cysts. Experience teaches that simple cysts associated with chronic mastitis when treated in this way by simple puncture but rarely

refill, although a similar cyst in a different portion of the breast may develop later. Should a cyst once tapped refill, further tapping is useless, and either local removal or simple mastectomy is required to effect a cure. I have personally never seen a case in which carcinoma has developed after the appearance of cysts of this kind, but Cheatle and others have described its presence in breasts removed on this diagnosis, and hold that in an unknown proportion of cases the process, which may cease at the stage of simple cyst formation in some regions, progresses elsewhere in the breast to cancer.

Conclusion

This brief survey of the outlook in non-malignant diseases of the breast suggests the following conclu-

sions. One only of their number—i.e., that form of epithelial activity which presents itself clinically as a duct-growth—is prone to malignant change and must be looked upon as requiring early surgical eradication. Of the inflammatory lesions only the specific ones, tuberculosis and actinomycosis, are of serious prognosis, when their appearance in the breast forms but a part of established disease elsewhere. And chronic mastitis, the clinical features of which are clearly defined and readily recognisable, is not a "pre-cancerous" condition, and even if intractable need not occasion alarm or the early resort to mutilating operative measures.

ERIC PEARCE GOULD, M.Ch., F.R.C.S.,
Surgeon to Middlesex Hospital.

SPECIAL ARTICLES

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

SECTIONS OF PUBLIC MEDICINE AND MEDICAL SOCIOLOGY

At a combined meeting of these sections, with Sir HENRY GAUVAIN in the chair, a paper was read by Sir RAPHAEL CILENTO (Brisbane) entitled

Racial Pressure Problems in the Pacific

Three propositions, he suggested, were mutually dependent. (1) Every previous culture has had its period of growth, vigour, and dominance; its period of arrest, stalemate, and disillusion; and its decline and fall. (2) Populations, as Malthus said in 1798, always tend to increase up to the limits of available subsistence, and indeed would inevitably do so were they not subject to the positive checks of war, disease, vice, and misery, and also to the prudential check of deliberate limitation. (3) In animals, plants, and also in societies evolution is both progressive and retrogressive constantly, and the specialisation to a particular environment which is a notable factor for advancement, becomes a fatal weakness when the environment is changed. Referring to the works of Oswald Spengler ("The Decline of the West," 1922), Sir Raphael said that Spengler's contribution was the demonstration that not only had the histories of all cultures a general similarity, but the course of each conformed so closely to one standard as to make all essentially identical. From ancient facts, therefore, present tendencies can in the gross be forecast. Spengler claimed that "all that is cosmic bears the hall-mark of periodicity."

The student of Spengler, he went on, would be struck by the fact that he makes no mention of disease or famine in the fate of cultures. The only sickness he knows is sickness of the soul, the only virility, that of the spirit. He seeks no physical stimulus in that "first stirring" towards progress in the basic barbarian mass; and for the fact that the life-blood of every culture pours away in an enormous decline of population he scouts any scientific explanation. He postulates as sufficient a metaphysical "turning toward death" seen only at the end of a culture and in city populations. Nothing was further from the truth. Rivers and others, in "Essays on Depopulation," had found precisely the same thing amongst the primitive savages in Oceania in their island atolls and forests. It was found, amongst the Pacific native cultures, that the

depression was secondary to sickness and under-nutrition. Population amongst these native races was found declining in places where native institutions flourished with all their original vigour, as well as where they had been destroyed; and the people were thriving in places where white men had entirely disrupted their social organisation, as they must inevitably disrupt it everywhere in the course of time. The factors operating adequately for decline were: (1) Introduced diseases, such as malaria, hookworm, and tuberculosis. (2) Faulty sanitation of environment. (3) Privation and poverty of diet. (4) Abortion and infanticide. Malaria and such chronic diseases were producing lethargy and bodily weariness which prevented anything but the most essential tilling of the soil or foraging for food, while the very poverty of the diet that resulted lowered the resistance to disease and so permitted more frequent disease, with constantly lessened food-supplies, until a point had been reached at which the human organism could no longer cope successfully with the situation. In the most sophisticated city and in the most primitive jungle, therefore, one saw identical results so long as disease and indigence ploughed the body and sowed despair.

Sir Raphael then reviewed ancient and contemporary history, in his examination of the status of women, and its relation to child-bearing. Depopulation and disillusion were merely the negative phases of the equally unbalanced ascent and expectancy of the population period. At the beginning of Queen Anne's reign (1704) the population of England was 6 millions, and only 1 million lived in the cities. In Malthus's day (1798) it had reached 11 millions, and the percentage in towns was doubled. Of the 105 towns of more than 25,000 people in England, 60 had come into being since 1825 (Ripley). The birth-rate increased somewhat in that eighteenth century, remained stationary until about 1876, when economic pressure made prudential limitation advantageous, and had declined persistently since. The death-rate fluctuated and then declined markedly as the fortunes of England rose with the Napoleonic wars. It followed that the great increase in population in this age of urbanisation was due largely to a decline in the death-rate and those favourable factors in environment that brought it about. The world of the nineteenth century was open to the exploiter; expansion was possible into many partly occupied territories, and potential markets lay on every side. A tremendous impetus was given to the Western peoples. In the Pacific it produced, inter alia, three "moonlight" civilisations, as

Spengler calls them, civilisations that take their light from a live source, and may even re-radiate it in a permanent form. They were the United States of America, Australia, and Japan. Japan, originally a "moonlight" offshoot of the Han civilisation of China (A.D. 220) definitely attached itself to the new light of Western civilisation in 1868, and will stand and fall with it. A Japanese culture per se there had never been except in an imitative sense, and the present Japanese Americanisation must not be regarded as Oriental on analysis. In the Pacific itself, our culture struck the Oceanic peoples with considerable violence. The old civilisations of the Dutch East Indies, with peace and increased productivity, responded by an increase of population from 8 millions in 1816 to 37 millions a century later; the specialised primitives of the Oceanic islands, on the other hand, lost 75 per cent. of their populations in two generations.

The apparent truth was, it seemed, that the population a country could support was the population it could provide with gainful employment. Was not this again merely the Malthusian "subsistence"? The rapid fall in the birth-rate, the declining proportion of youth, and with it the declining proportion of potential mothers, were all actually correcting the disparity between population production and consumption in all civilised lands except Italy, Russia, and Japan. This probably meant a new inevitability of conflict with or between these other Powers and a loss of frontiers and culture. The population of Japan had increased in 60 years from 28 to 60 millions. It had now reached saturation point. The density of population represents four persons to the acre of arable land, and is increasing. It appeared inevitable that on the present figures, Japan proper would reach a population of about 113 millions in 1967, at which period England and America would have reached their period of stalemated decline—and with them Australia. The lack of balance in the diet was of vital importance. In Australia the figures were generally unfavourable. The average age of the population was rising rapidly, and the proportion of youth declining. The natural increase for 1931 was half that for 1891. At the present rate it had been estimated (Exley) that the stable population of Australia was not more than 8,500,000, with excess females of 35 per 1000. The solution was immigration or ultimate invasion.

After reviewing the world situation generally, Sir Raphael concluded by emphasising the essentials of health and the dominant mentality, the requirements to ensure survival in the forthcoming period of increased pressure in the Pacific.

DISCUSSION

Sir JAMES BARRETT (Melbourne) said that in the Pacific the experience with imported labour had been that each race in turn left the fields and went into the city. In Fiji there was a remarkable institution of the native medical school, with four years training. It was run by the Rockefeller Institute and British Government combined. There was, he said, nothing physiologically speaking to prevent the white race from settling in Northern Australia. The birth-rate was better than in the southern cities, and there was practically no tropical disease. The reasons for failure to develop had so far been economic. In the Northern Territory, the rainfall was less than that required, and there could be no pastoral industry until irrigation was practicable. There had been about 70 million pounds spent on the development of Northern Territory and the present popu-

lation was about 4000. The maximum area of land suitable for cultivation in Australia was about one-eighteenth that of the United States of America. Great tracts of land in Queensland were suitable for pastoral and mineral development only. The greater part of tropical Australia would never be inhabited by us, or any other race.

Dr. D. G. CROLL (Brisbane) thought that Spengler's theory was unacceptable—the fault was the assumption that the present European culture was analogous to others. The present age differed from any other; it was the scientific age and had lasted about 100 years. The dangers from our Pacific neighbours should not be under-estimated. We must increase our population by the combined methods of immigration and raising the birth-rate. A full health service was the best safeguard for the future; the modern conception of health embraced the whole of the personality.

Rev. JOHN FLYNN (Sydney) asked: "Does history repeat itself?" Not entirely, as conditions alter from time to time. An international outlook was essential. It was hard for visitors to realise the size of Australia—one cattle station was larger than the whole of Switzerland! The settlement of Australia was dependent on meteorological factors.

Sir RAPHAEL CILENTO, in reply, deplored the tendency to emphasise the "desert complex" in Australians. The rich coastal fringe of Queensland, which had been described as the only fertile part of Northern Australia, was in acreage larger than the sub-tropical parts of Southern Australia. Science enabled impossibilities to become possibilities, and it was on these latter that we should dwell.

Tropical Medicine

Sir Raphael then took the chair, and Dr. G. CARMICHAEL LOW (London) surveyed briefly some of the great discoveries made in tropical medicine since the beginning of this century. These discoveries had led to vast improvements in the health of those residing in tropical countries, and incidentally to the recognition of tropical medicine as a special branch of medical science. Diseases peculiar to the tropics differed in many respects from those found in temperate zones, and it was this difference, combined with lack of knowledge on these subjects, which had led Sir Patrick Manson to institute special schools for the study of what is now known as tropical medicine. Though this term had been applied to a particular branch of medicine it should be remembered that those desirous of practising in the tropics needed a sound foundation of general medical knowledge. Many diseases, such as sprue and yellow fever, were restricted to the hot parts of the globe, whilst others such as malaria, dysentery, and cholera, although occurring in non-tropical climates, were much more common in the tropics. Another feature of tropical diseases was their transmission by insects, whilst protozoal and helminthic parasites were very important in aetiology. Hence the student wishing to understand tropical medicine needed a special training in entomology, protozoology, and helminthology.

Dr. Low referred to the growth in Europe of institutes for the study of tropical diseases, following the establishment of schools in London and Liverpool. Now America had schools, the three services all had special courses, and recently institutes had been founded at Bombay and Sydney. This development was reflected in the outlook of patients suffering from diseases such as trypanosomiasis and kala-

azar, who could now be successfully treated. In the past thirty-five years advances had taken place which rivalled those in any other branch of medicine. Dealing first with filariasis, Dr. Low said it was Dr. Joseph Bancroft, of Brisbane, who discovered the adult forms of the parasite in a lymphatic abscess of the arm in 1876. Cobbold, to whom the worms were sent for identification, named the parasite *Filaria bancrofti*. Yellow fever had been shown by the American Commission in Havana in 1901 to be spread by mosquitoes, and the causative agent to be a filtrable virus. This enabled the construction of the Panama canal to be completed, and the disease had been practically extinguished from the New World. Work on this disease in Africa by the Rockefeller Commission had greatly advanced our knowledge of the infection, whilst the work of Theiler, fixing the virus for the brain of mice, enabled protective inoculations to be made available for those proceeding to affected regions. The problems of trypanosomiasis and kala-azar—"black fever" of India—had also been solved early in this century, whilst ankylostomiasis and bilharziasis were helminthic diseases in which our knowledge had been notably advanced. Undulant fever, a great debilitating disease in our Mediterranean fleet, had been traced to infected milk.

Perhaps the greatest discovery in tropical medicine was that of the intravenous method for the administration of preparations of antimony (tartar emetic). It had enabled us to control trypanosomiasis (partly), kala-azar, ulcerating granuloma, and bilharziasis, and to rob these terrible diseases of their terrors. Credit was due to Broden and Rodhain for this revolution in therapeutics. In 1907 a second plague commission, by a series of careful experiments, had shown that the rat and its fleas played an important part in the spread of plague, the disease being transmitted from rat to man by the bites of rat-fleas. There had been little advance in the development of treatment. The conquest of beri-beri had been another triumph for tropical medicine—its incidence had been reduced to practically nil. The utility of emetine in amoebic dysentery had been well established, and liver abscess was now very rare.

Turning to the future of tropical medicine, Dr. Low said that many problems awaited solution—for instance, blackwater fever and sprue. Future discoveries would probably be made in the realms of biochemistry and experimental laboratory research. Tropical medicine was of paramount importance to Australia and the mandated territories, and the success of any enterprise in a tropical country was directly proportionate to the extent to which tropical diseases were controlled by a proper practice of tropical medicine in all its aspects.

Dr. C. L. PARK (Singapore), director of the Eastern Bureau, Health Organisation of the League of Nations, followed with a paper on the

INCIDENCE OF DISEASE IN EASTERN COUNTRIES

He agreed, he said, with Dr. Low that there was increased prevalence of certain diseases in the tropical countries. It was the prevalence of what were termed the major infectious diseases—plague, cholera, and small-pox—in Eastern countries and the lack of exact information in regard to their occurrence that had induced the League of Nations, in 1925, to establish an epidemiological intelligence bureau in Singapore. This bureau was kept informed by cable of the development and course of such diseases in every country throughout the East, and disseminated this information by wireless and cable.

Plague in the East existed in three main centres—India, the Netherlands Indies, and China. In India the mortality had fallen from 1,170,000 in 1907 to 30,000 in 1930. Epidemic prevalence was in the Punjab and United Provinces, whilst Bombay was the principal endemic centre. It would be noted that the absence of epidemics from Punjab had accounted in great part for the fall in mortality between 1927 and 1931. There was a definite seasonal prevalence, particularly marked in Punjab and United Provinces. The maximum seasonal prevalence in Bombay corresponded with the minimum in the epidemic areas. Webster's work in Bombay and Madras indicated that it was the "blocking" phenomenon that was influenced by climate—more infected fleas becoming "infective" when conditions were favourable. In the Dutch Indies the evolution of plague was demonstrated in Java. Introduced in 1911 via Soerabaya, it persisted in epidemic form in the interior of East Java until 1915. After a free period, extending to 1918, a further introduction, via Semarang, led to the infection in epidemic form of Mid-Java, which persisted until 1928. Subsequently West Java became infected via Cheribon, and now the disease was mainly confined to the mountainous districts of Bandoeng and Garoet, in Western Java. It had thus taken twenty years for the disease to reach West Java, and it was noticeable that there had been no tendency to recrudescence. The seasonal prevalence in Java did not correspond with that in India, the maximum period being reached in December in the wet season in Java, as compared with the March-April maximum in India, which is the dry season. In China there were three active centres—in Fukien, in Shensi-Shanis area, and in Manchuria. In each of these areas the disease was of bubonic type, and the *X. cheopis* was the vector. The opening up of roads and railways in the north, which was rapidly proceeding, might be the means of disseminating the disease. Control measures were: in India, the use of Haffkine's vaccine as preventive measure, along with the application of specific anti-rat measures; in Java, house reconstruction was carried out to destroy and prevent rat harbourage. In addition, large-scale mass inoculation was being used with a living avirulent vaccine prepared by Otten, in Bandoeng. High immunity was obtained. As regards transfer from one country to another, prevention consisted of measures of deratisation applied regularly and rat-proofing of vessels.

Cholera.—The mortality in India was shown to fluctuate from year to year, but the general trend was downward. The cholera season in India generally was the monsoon season, except in Bengal. Epidemic cholera was associated with high relative humidity. Control measures included a piped public water-supply, inoculation and use of bacteriophage. The value of the last-named was uncertain but it did reduce infectivity and hence indirectly epidemic spread.

Small-pox.—India was again the principal focus. Particularly favourable were figures from Java where in 1932 only 39 cases occurred in a population of 42 millions; also in Japan. This was due entirely to systematic vaccination and revaccination.

The control of malaria was, Dr. Park concluded, essentially a local problem.

In the discussion which followed Dr. F. W. P. CLOVER (Durban), Dr. E. T. BRENNAN (New Guinea), Prof. HARVEY SUTTON (Sydney), Prof. J. A. GUNN

(Melbourne), Dr. J. S. PURDY (Sydney), and Dr. A. G. BUTLER (Duntroon, F.C.T.) took part.

Dr. Low, in replying, stressed the use of quinine as a prophylactic against infection with malaria.

Weil's Disease

Dr. T. J. COTTER (Townsville, Queensland) gave an account of the outbreak of Weil's disease in North Queensland in October, 1933, the first known occurrence of the disease in Australia. In fatal cases death occurred between the eighth and the fifteenth days. Convalescence was sometimes very prolonged. Patients were all healthy adult males, workers in the cane-fields. There was no record of case-to-case infection. Heavy rat infestation was present on the fields. *Leptospiræ* were isolated from 30 per cent. of rodents examined and the pathogenicity established by guinea-pig inoculation. Dr. Cotter stressed the importance of the disease from both the health and the economic aspects. Rat infestation must be fought by repeated poisoning campaigns and clearing of harbourage. The question of prophylactic inoculation (vaccination) was worth consideration.

SECTION OF SURGERY

At a meeting of this section presided over by Sir CARRICK ROBERTSON (New Zealand) a discussion on

Prostatectomy

was opened by Mr. A. CLIFFORD MORSON (London). Radical cure, he said, was the ideal to be aimed at in adenomatous disease of the prostate; incomplete removal of the diseased portion of the gland resulted in recurrence. For this reason he was not in favour of transurethral methods; the patient was not permanently relieved of his symptoms. The Harris technique was, he thought, a definite advance on those of Freyer and Thomson-Walker. Not only was it a hæmostatic operation, but an attempt was made to obtain healing by first intention within the prostatic cavity. The post-prostatic pouch was obliterated by drawing down the base of the bladder to the level of the bed of the prostate; and, lastly, the bladder could be closed and the patient relieved of an otherwise uncomfortable convalescence. With the urethroscope and cysto-urethroscope he had observed the changes in the bladder and the urethra after the Harris operation. If there had been failure to unite the trigonal flap to the torn edge of the urethra, healing was by second intention. This area, which in his own cases varied from one to five millimetres, healed very slowly, taking up to six weeks, although the abdominal wound had already healed and micturition was almost normal. Pyuria persisted so long as there was an internal wound. Mr. Morson said he had adopted the Harris technique with certain minor modifications. An anterior lighted retractor was used together with a prostatic speculum. The speculum gave perfect visibility of the prostatic bed, and by compressing the vessels, produced hæmostasis whilst the sutures were being inserted. He preferred a figure-of-eight stitch to the anterior transverse sutures used by Harris, because it acted as a better hæmostatic and produced a better closure of the cavity. Division of the vas guaranteed avoidance of epididymo-orchitis. As well as this he attempted to sterilise the seminal vesicles by irrigation through the proximal end of the divided vas with 1 in 60 carbolic acid. There was a danger of secondary hæmorrhage if there had

been failure to approximate the trigone to the fractured urethral end. It usually occurred about 24 hours after the removal of the urethral tube. It responded readily to hot irrigations or suprapubic cystostomy.

Mr. JOHN TAIT (Melbourne) said that asepsis was essential in the Harris operation and this was difficult to obtain in all cases. The methods used to control hæmorrhage were packing, Pilcher's bag, and suture; and of these suture was ideal. With the use of the latter the danger of primary hæmorrhage had been abolished, although he remembered one fatal case following too early application of suction drainage. Secondary hæmorrhage still occurred on separation of the sutures. He believed that one of the factors in secondary hæmorrhage was early closure of the bladder, and he therefore kept a small tube in the bladder until after the fourteenth day. He agreed that it was important to divide the vas but the difficulty was to do this at the correct time.

Mr. F. MACKAY (Auckland) stated that the older methods had an evil reputation with the public, and this probably accounted for the sudden influx of transurethral methods which were not curative. He regarded the Harris operation as the ideal, but reserved it for adenomatous enlargement. Endoscopic methods were used for the fibrous and malignant prostates. Even after prolonged suprapubic drainage the Harris technique could be performed. Strict attention to the details advocated by Harris was essential for the success of the operation, particularly with regard to asepsis.

Mr. G. H. BURNELL (Adelaide) discussed the value of renal efficiency tests. The blood-urea test was inefficient and he relied upon the Thomas modification of the indigo-carmin test. A series of successive tests was of great value. If only one test was done it should be performed only after seven to ten days' catheter drainage. He strongly advocated the Harris technique. He always brought the trigonal stitch back through the apex of the trigone to prevent buckling. The vas was always ligated. Results from the Adelaide Hospital showed a mortality of up to 18.8 per cent. for non-sutured operations. With sutured operations the mortality was 4.9 per cent. In a small series using the Harris technique there had been no deaths.

Mr. RICHARD HARRIS (Sydney) regretted that his brother was unable to be present. Speaking on his behalf he wished to point out that their success had been due to rigid attention to detail. The mortality in 547 cases was 2.7 per cent. The incision was always a transverse one two inches above the symphysis pubis. Closure of the abdomen was not safe with a vertical incision. He claimed that by the intra-urethral enucleation of the gland, the verumontanum was left intact. They had found that by use of the Harris retractor the prostatic cavity could be seen perfectly well without any additional modification. He emphasised that the plastic was not by a flap of trigonal mucosa but by the whole thickness of the trigone. The anterior transverse sutures had been used satisfactorily and he preferred them to the figure-of-eight suture which tended to produce sloughing. The indigo-carmin test was relied upon solely after seven days' catheter drainage.

Mr. C. ROCHE (Melbourne) advocated the use of the resectoscope for selected cases, especially fibrous prostates and mild adenomatous disease.—Mr. P. GILL (Perth) supported the Harris technique, but

emphasised the importance of deep X ray therapy in some adenomatous glands.—Mr. JOHN KENNEDY (Melbourne) asked whether the figures given by Mr. Morson and Mr. Burnell were of selected cases. He considered that it was important in old people particularly to get the patient off the table quickly. In these cases he relied upon Pilcher's bag.—Sir HENRY NEWLANDS (Adelaide) noted with approval the post-operative investigation conducted by Mr. Morson. It was irrational to expect primary healing with digital removal.

Mr. MORSON, replying, said that he did select his cases; it was useless to perform prostatectomy on the nearly moribund. He was glad to hear that transurethral methods had not gained support in Australia. They were of some use in fibrous and malignant prostates, but even in the latter he thought suprapubic cystostomy was preferable. He had found that retention of urine followed the use of X rays in these cases. In reply to Mr. Richard Harris, he said that Mr. Harry Harris had watched his use of the figure-of-eight suture with approval.

With Mr. F. C. PYBUS (Newcastle-on-Tyne) in the chair, a discussion on

Carcinoma of the Colon

was opened by Mr. H. B. DEVINE (Melbourne). The problem before the surgeon in carcinoma of the colon was to reduce the high operative mortality, which ranged between 15 per cent. and 57 per cent. in well-equipped clinics. The disease was a relatively benign type of malignancy, and if the operative mortality-rate could be improved, it would be the one malignant disease eminently curable by surgery. He proposed to direct his remarks to carcinoma of the distal colon; he wished to state, however, that it was his practice in carcinoma of the proximal colon to employ an enterotome method rather than the sutured anastomosis of ileum to transverse colon. The technique had been published in THE LANCET (1931, i., 627). In carcinoma of the distal colon one of the main factors in the high operative mortality was the presence of intestinal obstruction, acute or chronic. The adverse pre-operative conditions which were present could be improved by:

- (1) Earlier diagnosis. He stressed particularly X ray methods showing a mucous membrane relief pattern.
- (2) Improvement of the patient's general resistance by intravenous therapy and transfusions.
- (3) Measures to combat the effects of intestinal obstruction. Routine colonic drainage should precede all operations for carcinoma of the colon and must be continued for an adequate time. The usual methods of drainage, caecostomy, and colostomy, with or without a spur, were ineffective because they did not completely and permanently disconnect the distal from the proximal colon.

The traditional methods of operation for colonic carcinoma were a sutured anastomosis and the Paul-Mickulicz technique. The former carried a very high mortality; the latter, though safe, was suitable only for carcinomata of the middle of the sigmoid or the transverse colon. In other situations the amount of bowel and lymphatic field which could be removed was inadequate. In cases which were not amenable to Paul's operation, Mr. Devine had devised a method of operating which he had employed with success. Its essentials were as follows:

- (1) The proximal and distal colons are "disconnected" at the transverse colon. The completeness of the disconnection is ensured by inserting the cut ends of the bowel into separate small openings in the abdominal wall.

(2) The "defunctioned" bowel is washed out with warm olive oil, so that the bacterial content was reduced.

(3) The growth and the correct amount of mesenteric leaf are subsequently excised.

(4) Closure of the "disconnecting anus."

In the upper part of the distal colon a sutured anastomosis can now be performed under aseptic conditions. In carcinoma near the recto-sigmoid junction the affected segment of the "defunctioned" distal colon is excised, the rectal stump closed and covered with peritoneum, and the cut end of the sigmoid implanted into the wound. At a later stage the anastomosis between the rectum and the sigmoid can be done without fear of failure. This anastomosis can be made by suture, but if the resection site is too low a telescopic method is used, the distal colon being drawn through the rectal stump.

Mr. V. HURLEY (Melbourne) said that most cases were seen too late, when intestinal obstruction or spread of the growth had occurred. He emphasised the importance of early diagnosis. Suspicion should be aroused by the presence of minor symptoms and signs, of which alteration in bowel habit was the most important. Occasionally upper abdominal dyspepsias and appendicitis were mimicked. Occult blood tests, routine sigmoidoscopy, and bimanual palpation were all necessary parts of the examination. Barium enema and barium meal, though essential, should not be regarded as the final court of appeal. Occasionally the administration of a barium meal was followed by faecal impaction and intestinal obstruction. Where intestinal obstruction was present he advised laparotomy and ileo-transverse colostomy for caecal growths; and proximal drainage, either colostomy or caecostomy, in the rest of the colon. In very ill patients caecostomy under a local anaesthetic was the operation of choice. He advocated the staged Mickulicz operation wherever possible. When mobilisation was difficult a sutured anastomosis with proximal drainage of the bowel was performed. The incisions could be planned so that the approach was directly over the growth. The anaesthetic for preference was local infiltration together with gas-and-oxygen.

Mr. ALAN NEWTON (Melbourne) agreed with the surgical procedures advocated by Mr. Devine for left-sided growths. With right-sided growths he preferred to perform an ileo-transverse colostomy. He could see no advantage in the Devine modification of the Mickulicz operation for these growths, as it was an equally long operation. Obstruction after a sutured anastomosis of this type was uncommon, but could easily be overcome by ileostomy under local anaesthesia.

Mr. JOHN RAMSAY (Tasmania) advised the Mickulicz operation for colonic tumours because of its ease and safety.

The CHAIRMAN (Mr. Pybus) spoke of the similarity of symptoms of these growths to those caused by the dyspepsias and by diverticulitis. Even at operation it was often difficult to decide between the latter and carcinoma. The real problem was one of early diagnosis. If this could be done, resection and suture could be performed with safety. He agreed with Mr. Devine's method of "defunctioning" the colon. Caecostomy gave very poor drainage. He suggested that special departments should be instituted at hospitals for the investigation of gastrointestinal cases.

Mr. DEVINE briefly replied to other speakers. He preferred a central incision to the incision centred

over the growth as suggested by Mr. Hurley. In answer to Mr. Newton, he said he thought his enterotome method for right-sided growths was safer than sutured anastomosis. The trouble with the latter procedure was not post-operative obstruction but infection at the suture line. He agreed with Mr. Pybus's statement that early diagnosis was the key to the problem, but until this was fulfilled he claimed that the methods he had advocated, particularly the "dysfunctioning" of the colon, would definitely reduce the operative mortality.

SECTION OF NEUROLOGY AND PSYCHOLOGICAL MEDICINE

At a meeting of this section, Prof. EDWIN BRAMWELL presiding, Dr. W. S. DAWSON (Sydney) opened a discussion on the

Psychoses of Adolescence

The subject, he said, was of importance, not so much by reason of the total number of cases occurring at this age-period, but because it was during adolescence that the first manifestations of two outstanding clinical syndromes appeared. The incidence of psychoses rose from the age of 15, before which insanities were infrequent. On the other hand, the history of some adolescent psychoses indicated that a change of disposition might occur several years before initiation of treatment. After the age of 20 the insanity-rate continued to rise more gradually. The onset of manic-depressive psychosis and dementia præcox showed a maximum incidence between 20 and 25 years of age. Epilepsy and delinquency showed a similar age-incidence pointing to a heightened instability at this period.

During adolescence body and brain attained their maximum development, although organisation of nervous structures proceeded afterwards. The activity of the endocrine system was increased and the sexual apparatus matured. The brain normally should function as the arbitrator between inner urges and stimuli derived from the exterior. It was probable that some forms of adolescent instability were due to unequal development of the controlling and impulsive mechanisms. Physique might outgrow prudence. An emotional disturbance, closely related to the transition from egocentricity to altruism, accompanied the physiological unrest of the period. Youth should be full of effort. The quiet passive adolescence was one that seemed most likely to develop the more serious psychoses. Erotic manifestations, provided they were kept within bounds, were less subject to repression and reprobation in these days. The classification Dr. Dawson suggested was:

- (A) Organic group .. Confusional psychoses.
Psychoses associated with epidemic encephalitis.
General paralysis and epilepsy.
- (B) Biogenic and functional group. Manic-depressive psychosis.
Dementia præcox or schizophrenia.

The confusional psychosis was not common in adolescence, apart from that accompanying an acute infective illness. Alcohol and the puerperium, common factors in later life, were not of much importance. Usually no previous psychopathic tendencies had been displayed, but a history of prolonged physical or mental distress was usual. In early and mild cases there was difficulty in concentration and an appearance of perplexity. Impairment of awareness of the environment was responsible for

suspensions of the actions of others. When the patient was silent or inaccessible, distinction from melancholia might not be easy. Some cases exhibited catalepsy and *flexibilitas cerea*. With the absence of any marked introversion the prognosis was good.

Closely associated were the mental disturbances of acute encephalitis, taking usually the form of a drowsy delirium, sometimes of the occupational type, with hallucinations or illusions of various senses. The organic signs usually but not always excluded a hysterical or psychotic stupor. Actual dementia might occur, as in neurosyphilis, but the striking features were deterioration of moral sense, and a proneness to impulsive violence uncommon in juvenile paresis. At times there was some difficulty in differentiating parkinsonism, melancholia, and catatonia; or again there might be a resemblance to neurasthenia or mild melancholia. Later the signs of prepyramidal disorder rendered the diagnosis clear. Attention to the mode of onset and the previous personality was of assistance. Such features as hallucinations, delusions, and oddities of behaviour common in dementia præcox were absent. Juvenile general paralysis accounted for only a small proportion of the psychoses of adolescence, the mental symptoms often resembling dementia præcox.

The term dementia præcox was first employed by Morel in 1860. Although well described by various observers, Meyer in 1906 opened new avenues to the understanding of the condition. He emphasised the importance of the distinction between fundamental and incidental symptoms. As fundamental he pointed to the lack of adaptability often displayed before the recognition of the actual psychosis. He also discouraged the emphasis on dementia. Part at least of the symptoms were due to a deterioration of conduct which was not beyond remedy. He and his pupils had attempted to define the prepsychotic traits. They found reticent seclusive unadaptable individuals, sensitive and passively stubborn; showing little interest in what was about them. They tended to live in a world of fancies. An emotional inadequacy was significant. Character development was liable to be stunted through the absence of social contacts. Unhealthy ruminations, sexual perversions, devotion to abstract study, religious exercises which savoured more of self gratification or of a maudlin sentimentality, were some of the undesirable accretions of introversion. This must of course be distinguished from the life of retirement and self-denial which was creative.

The manic-depressive group had also a hereditary and constitutional background. The incidence was greatest in adolescence and early adult life. In the prepsychotic personality there was often evidence of depressive and hypochondriacal trends. In a series of cases with depressions of all intensities, the speaker found that a third had a history pointing to marked introversion. The typical features of this psychosis in adolescence were hypochondriacal complaints and fears in depressed cases; and exaggerated egotism and over-confidence of personal capacity, with intolerance of discipline, and erotic trends, in maniacal cases.

Many of the cases could not be pigeon-holed into any of the above two categories, some showing features of all types. Our difficulties might arise from attaching an exaggerated importance to a minute analysis of ideation and behaviour, without proper reference to personality and circumstance. The more normal the individual, the richer his

interests; the greater the previous physical and mental stresses, and the more rapid the onset of mental symptoms, the better the prognosis. The principles of treatment laid down by Clouston in 1891 should not be departed from. "Build up the bone and fat and muscle" and "rather restrain the imaginative and artistic faculties and sensitiveness and idealisms generally, in the cases where such tend to appear too early and too keenly. . . . Cultivate and insist on orderliness and method in all things." Using Hughlings Jackson's phrase, there is usually some "intact remainder" to work upon. The recognition and correlation of anomalies of character and temperament during the school years, and the examination of the children of psychotic parents, offered a possibility of preventing or arresting more serious mental abnormalities.

Prof. K. H. BOUMAN (Amsterdam) dealt with schizophrenia as a form of genetic regression. Alzheimer in 1900 made clear that a loss of cells in the supragranular layers of the cortex occurred in dementia præcox. Nissl, Josephy (1922), Naito (1924), Bouman (1924-1928), Hechst and Miskolczy and others came to the same conclusion. It was a disease of cortical origin in which the ganglion cells underwent fatty degeneration and sclerosis and disappeared, the glia not usually being active. The third layer was most affected, but also the others, especially the fifth. Where clinically severe agitation had been present we might find glial activity, ganglion cells loaded with lipid, and blood-vessels surrounded with fatty substance. The disturbance of higher motor function—e.g., hyperkinesia, akinesia, katalepsia, katatonia—suggested that the striatal region might play some part in the disease. The speaker by cell counts of the cortex believed that there was a loss of cells in all the layers in the order 3, 2, 5, 6, and 4. Miskolczy gave the order as 3, 5, 6, 2, and 4. There must be a close connexion between structure and function. Kappers believed the functions of the six cortical layers to be as follows: layer 1 conducted the functions of the senses; 2 possessed short intracortical and receptive functions; 3 was an association of longer intercortical connexions; 4 had chiefly a complex receptive function; 5 and 6 a system of motor conduction. Layers 2, 3, and 4 therefore formed a place where afferent impressions were translated into motor activity. The third layer was young phylogenetically and ontogenetically. The main areas of cortex affected in schizophrenia were those peculiar to man. Mott's demonstration of alteration in the sexual glands, together with these changes, suggested an insufficient progenerative power of the matrix material of both tissues. The anatomical regression of the cortex created an organism with more primitive modes of thought, in which causal and logical relations disappeared.

Representatives of modern psycho-analysis, as Jung and Abraham, supposed the symptoms of schizophrenia to be connected with very early emotional experiences. The idea of regression was an essential part of all these considerations and studies; but in the psychoses, regression went back to a much earlier stage of psychological evolution than in any neurosis. There was a break between the ego and the world outside; fancy and reality flowed together, and the psyche retreated into a world of its own where very primitive forms of thought ruled. This was the world of the primitive, where reigned the myth; the world of the dreamer, the young child, the artist, and the schizophrenic as well.

DISCUSSION

Dr. A. W. CAMPBELL (Sydney) from his experience of practice in both England and Australia was of the opinion that the prognosis of the mental disorders of adolescence was rather better in this country, where living and climatic conditions are better. He confessed himself unable to foresee insanity in the young; and he thought the school-teacher best placed to undertake this early study.

Dr. C. FARRAN-RIDGE (Melbourne) dealt with the problem of the prevention of dementia præcox, apart from eugenic measures. He said that in the case of persons in whom the predisposition was strong, no environment however favourable, no training however well directed, would suffice to avert the development of the disorder. In the case of persons in whom the predisposition was of moderate strength shelter, guidance, and habits of training would sometimes prevent a breakdown. If the predisposition were slight the patient could often be helped to go further and accomplish more than if left unaided. The instinct in which he would be most lacking was that of pugnacity, and he should accordingly be made to realise the impossibility of getting through life without fighting.

Dr. J. K. ADEY (Melbourne) raised the question of the prognosis in dementia præcox. Some recovered, and he wondered if these could be separated from the incurable group. Forty per cent. of all primary dementals dying in Victoria showed small hands and narrow aorta. Cyanosis of the hands, even in warm weather, was common. He had recently taken skiagrams of the hearts of 45 primary dementals belonging to the silent non-violent group. Of these, 12 showed small hearts and cyanotic hands, and had not recovered; of the remaining 33 there had been 6 recoveries. He believed therefore that an X ray examination had some value in prognosis.

Dr. J. F. WILLIAMS (Melbourne) dealt with the pre-psychotic personality. It was difficult to distinguish types of personality which might become psychotic. He pointed out the value of the nursing schools at the hospitals. Personality defects might be modified in these schools, which were valuable for both difficult and prepsychotic children. Such defects as negativism, complete withdrawal and lack of interest might melt away in such an environment.

Prof. J. P. LOWSON (Brisbane) dealt with the psychological treatment of the accessible case. He thought that the psychoses were not nearly so unmodifiable as some years ago. Some may be reduced to the level of a neurasthenia. To accomplish anything one must be prepared to keep at them.

Dr. H. F. MAUDSLEY (Melbourne) remarked that many adolescents passed through a stage resembling schizophrenia and recovered to live normally. He distinguished certain types: (1) an acute pernicious type without prodromata; (2) a subacute type with remissions and exacerbations; (3) a type that was clinically cured.

NEW HOSPITAL FOR HERNE BAY.—The foundation-stone of a new hospital for Herne Bay was laid on Sept. 27th, when the dedication ceremony was conducted by the Bishop of Dover. The hospital will provide accommodation for 34 beds and it will be possible to add a further 50 later if they are needed. It will cost about £18,000, of which £13,500 has already been raised.

THE WAR MENTALITY

AN ADDRESS TO STATESMEN

WHAT follows is the text of a letter sent by 350 psychiatrists and psychologists to "all the statesmen of the world." It is issued from Haarlem by Dr. J. Roorda, hon. secretary of the committee for war prophylaxis of the Netherlands Medical Association. The names reproduced below are those of signatories in the British Isles:—

TO THE STATESMEN

SIR,—We psychiatrists, whose duty it is to investigate the normal and diseased mind, and to serve mankind with our knowledge, feel impelled to address a serious word to you in our quality of physicians. It seems to us that there is in the world a mentality which entails grave dangers to mankind, leading, as it may, to an evident war-psychosis.

War means that all destructive forces are set loose by mankind against itself. War means the annihilation of mankind by technical science. As in all things human, psychological factors play a very important part in the complicated problem of war. If war is to be prevented the nations and their leaders must understand their own attitude towards war. By self-knowledge a world calamity may be prevented.

Therefore we draw your attention to the following:

1. There is a seeming contradiction between the conscious individual aversion to war and the collective preparedness to wage war. This is explained by the fact that the behaviour, the feelings, the thoughts of an independent individual are quite different from those of a man who forms part of a collective whole. Civilised twentieth century man still possesses strong, fierce, and destructive instincts, which have not been sublimated, or only partly so, and which break loose as soon as the community to which he belongs feels itself threatened by danger. The unconscious desire to give rein to the primitive instinct not only without punishment but even with reward, furthers in a great measure the preparedness for war. It should be realised that the fighting-instinct, if well directed, gives energy for much that is good and beautiful. But the same instinct may create chaos if it breaks loose from all restraint, making use of the greatest discoveries of the human intellect.

2. It is appalling to see how little the peoples are alive to reality. The popular ideas of war as they find expression in full-dress uniforms, military display, &c., are no longer in keeping with the realities of war itself. The apathy, with regard to the actions and intrigues of the international traffic in arms is surprising to anyone who realises the dangers into which this traffic threatens to lead them. It should be realised that it is foolish to suffer certain groups of persons to derive personal profit from the death of millions of men. We come to you with the urgent advice to arouse the nations to the realisation of fact and the sense of collective self-preservation, these powerful instincts being the strongest allies for the elimination of war. The heightening of the moral and religious sense in your people tends to the same end.

3. From the utterances of well-known statesmen it has repeatedly been evident that many of them have conceptions of war that are identical with those of the average man. Arguments such as "War is the

Supreme Court of Appeal" and "War is the necessary outcome of Darwin's theory" are erroneous and dangerous, in view of the realities of modern warfare. They camouflage a primitive craving for power and are meant to stimulate the preparedness for war among the speaker's countrymen. The suggestive force of speeches made by leading statesmen is enormous and may be dangerous. The warlike spirit, so easily aroused by the cry that the country is in danger, is not to be bridled, as was evident in 1914. Peoples, as well as individuals, under the influence of suggestions like these, may become neurotic. They may be carried away by hallucinations and delusions, thus involving themselves in adventures perilous to their own and other nations' safety.

We psychiatrists declare that our science is sufficiently advanced for us to distinguish between real, pretended, and unconscious motives, even in statesmen. The desire to disguise national militarism by continual talk about peace will not protect political leaders from the judgment of history. The secret promoters of militarism are responsible for the boundless misery which a new war is sure to bring.

International organisation is now sufficiently advanced to enable statesmen to prevent war by concerted action. Protestation of peace and the desire for peace, however sincere, do not guarantee the self-denying spirit necessary for the maintenance of peace, even at the cost of national sacrifice. If any statesmen should think that the apparatus to ensure peace is, as yet, insufficiently organised, we advise them to devote to this purpose as much energy and as much money as is now being expended on the armaments of the various countries.

We cannot close without expressing our admiration of those statesmen who show by their actions that their culture and morality are so far advanced that they can lead peoples to a strong organisation of peace. In our opinion they alone are truly qualified to act as the leaders of nations.

We have the honour to be, Sir,

Your obedient servants,

POST-GRADUATE LECTURES

Our last two issues have contained summaries of lectures delivered at the autumn post-graduate courses in London, or extracts from them. This week we publish abstracts of two lectures given at Charing Cross Hospital by members of the honorary staff.

THE CHRONIC ABDOMINAL INVALID

(MR. C. JENNINGS MARSHALL)

OF all chronic illnesses there can surely be none that offers such a series of diagnostic anxieties in the first place, and therapeutic problems in the second, as does Glénard's disease. The first care is always to see that no organic disease has intruded into this maze of functional symptomatology—itself so characteristic and easily recognisable, but nevertheless treacherous in its mimicry of organic lesions.

DIAGNOSIS

There is a mixture of general and local manifestations—always a suggestive point. Vague pains in head, back and limbs, lassitude, and vasomotor symptoms such as flushing, throbbings, palpitation, dyspnoea, are combined with flatulence, vague indigestion, general or local abdominal discomfort, constipation, and symptoms mimicking any of the diseases of the stomach, duodenum, caecum, appendix, kidney, liver, or gall-bladder. The kypholordotic stance, with protruberant lower abdomen and fixed upper recti, is characteristic; the general suggestion of atony is belied by the readiness with which the musculature goes into rigidity on palpation. Physical signs may indicate a low position of one or many viscera, and confirmation is obtained radiographically. Local spastic contractions of gut are often felt.

Differential diagnosis clearly must provide against an almost inclusive abdominal index; in the main we fear most an alimentary cancer; most of us probably will recollect a case or so of overlooked carcinoma coli labelled enteroptosis on the strength of a negative barium enema and a radiogram of a transverse colon near the pouch of Douglas. (I wonder how many thousands are wearing belts for the same reason.) Radiography has nowadays reached a very high pitch of accuracy in the hands of the expert; but it has not attained 100 per cent., and there is a small proportion of cases, already perplexing clinically, that become confusion worse confounded with an equivocal X ray appearance. Radiography is done an undeserved wrong when infallibility is claimed for it, this in particular referring to the ability to *exclude* disease. There is fortunately for our peace of mind the extremely simple faeces test for occult blood—a persistently negative finding is of value, three or four negatives practically excluding an alimentary carcinoma.

Extensive investigations on the whole are harmful, they suggest and "fix" symptoms; often, however, it is necessary to perform one or more of the quadruple radiographic "overhaul"—barium meal, barium enema, cholecystography, and Uroselectan urinary investigation. These will establish the diagnosis in a large proportion of chronic abdominal lesions—peptic ulcer, gall-stones, diverticulitis, alimentary cancer and other obstructions, and gross renal and ureteric disease, besides letting us have a very useful peep at the spine for carious or aneurysmal erosion, for spondylitis or carcinomatous deposit, or to

note that frequent cause of symptoms, glandular calcification.

The proper analysis of cases of Glénard's disease needs leisure, detachment, and freedom to let the patient "have her head"; for it is essential to arrive at a more accurate conclusion than enteroptosis.

PATHOGENESIS

The subject has been dealt with exhaustively and extensively, both before and after Glénard's voluminous treatment in the last decades of the past century. The sum of achievement is that the pathology has been completely established and then just as completely demolished a dozen times. In general the chief thing is the recognition that its beginnings are not in the abdomen; exploded are such explanations as dropping of stomach and other viscera, mechanical interference by bands and kinks, "hepatism," parietal weakness, diaphragmatic fixation, and (one mentions it with trepidation) constipation. The latter in particular needs special reference; for poisoning by delayed faeces is a theory so universally accepted, so eternally preached day in and day out by a most motley series of interests—e.g., the paraffin kings, the pillmakers, the wholemeal bakers, the fruit merchants, and the syringe manufacturers—that it needs courage to point out, a fact of particular importance with regard to Glénard's disease, that constipation is a very versatile producer of symptoms but it is practically negligible as a cause of disease. The subject is controversial, but I cite merely two facts—the complete and absolute relief of symptoms with clearance of the bowel and the uniform failure to find toxins in normal faeces.

Some of the features of enteroptosis seem to suggest that allergy may play some part; no doubt there are often food idiosyncrasies in association with the disease, but this is probably accidental and not inherent. Many facts point to the neurogenous nature—the spastic type of gut manifestation in which the colon may be felt contracted as it is seen under spinal analgesia, the features of "mucous colitis," and the radiographic observation of variations in the alimentary canal under emotional changes. Many points are in favour of the "general hypotonus" view; other features are spastic and resistive and ill in accord with this. Certainly the basal lesion is psychical, though perhaps only in the vulnerable hypotonic individual. It may occur in either sex in childhood, where the behaviourist school would see the disease as an ill-conditioned reflex; still more frequently in sexual adolescence and in the early years of matrimonial misfits; and also from uncongenial circumstances and occupations. No one invariable nervous lesion is found—there may be hysteria, obsessions, phobias, and occasionally true neurasthenia—apart from the many aspects of the inferiority complex and mental maladjustments of numerous kinds. Whether the disease abdominally is a general reaction to all kinds of functional disturbances or whether it is associated particularly with one type of nervous constitution is a question which seems best answered by the latter explanation.

TREATMENT

Clearly this disease calls for psychical rather than physical treatment; and it is a condition in which the family practitioner is at great advantage compared with anyone else, both for his special knowledge of circumstances and his facilities for unhurried and

undisturbed ministrations. Above all, *these folk should not be allowed to get to hospitals*, this is fatal to the hope of cure or even of amelioration. In the nature of things, cure can rarely be expected; it is not in the power of the practitioner to alter the milieu, undo the matrimonial misfits, or correct the "conditioning" of childhood. For the sex worries of adolescence the customary teaching of hard exercise, sublimation, and cold water is more effective in theory than in practice, as was pointed out by the great Parish Priest. Often it is better to preach the virtues of resignation: taking arms against a sea of troubles does not end them (there are plenty of proverbs to help), and it is the rebellious and resentful mind that suffers. But it must not be suggested to the patient that the defect is mental; this is both insulting and an indication that the doctor does not understand the case and clearly calls for a change of adviser; we must be careful about counselling psychiatry or psycho-analysis. Equally destructive of confidence is any tendency to poo-h-poo the abdominal manifestations; the attitude to take is that all the patients' sufferings must be attended to and relieved although there is nothing progressive or lethal present.

Belts are prescribed for this condition for the purpose of supporting the abdominal muscles, and of keeping the viscera up. It is readily demonstrated radiographically that almost all belts press the bowels farther and more firmly into the pelvis—admittedly the stomach is often kept up, but this does not matter anyway—but it is often found they give relief. The symptom relieved is the backache, and the belt is acting as a sacro-iliac brace, which is a better prescription. Mainly however the belt is a mental support. The prospect of relief from a belt should be tried out by the experimental use of a very firm binder round hips and abdomen with the hips well raised during application. Like arch supports for the feet, the belt induces further muscular atrophy and effectively prevents any recovery of tonus. The logical alternative has been and is urged by Goldthwait and his school; but if it is obvious that this aspect of the case should be treated by exercises, it is equally obvious that the tired patient must start at small things, never doing enough to exhaust. The ordinary bedroom "on-the-back legs raise" type of gymnastic is suitable and universally applicable.

Surgery has no place in the treatment of the disease: I am aware that the stomach, liver, kidney, and colon stitchers, the appendicetomists, and the adhesion-dividers still claim results; they well can, for there is almost always improvement for six months or so—and then it is time to do something fresh. Only urgent and imperative surgery should be done, but there is one exception to be made to this rule: the constipation of the disease is frequently accompanied by piles or fissure, and it is certainly necessary to break the vicious circle constipation—painful defecation—more constipation—severe pain. Constipation must be treated as it produces symptoms; carefully adjusted dosage of paraffin is most useful, but often the paraffin is passed unmixed with faeces, and such cases need a gentle regular aperient. (There are many elegant preparations; pills of the aloes, strychnine, and belladonna type, or the homely senna pod, will be found perfectly effective and easily regulated.) Many cases become enema-addicts, often incurably, so that leaving-off causes great distress; the "colon laundry," as the Americans call it, is a flourishing vested interest (no novelty

however, for it finds a place in Indian medicine ages B.C.) which apparently pleases a lot of patients, and we had best leave it at that. (This is not to say that lavage has *no* uses, but certainly that it should become a fixed habit.)

Flatulence is a common and distressing symptom, it can be dealt with by the homely peppermint water and baking soda; and also prevented by avoidance of excess carbohydrate and of rich meat in the diet. With regard to the latter, most of the patients are under-nourished and are benefited by plenty of butter and cream. While the popular idea that regularity of meals is essential to health is a ridiculous myth, there is no doubt that regularity of meals for these patients is excellent both as an article of faith—"an act whereby they may be saved"—and also as a means of getting them to eat more. With all deference to the Great Roughage Creed, this fraction of the food is most distressing to the enteroptotic and all fruit with skins, pips, fibres must be avoided. A very important point is that plenty of fluid must be taken both during and between meals (fluid with meals causes not the slightest harm despite the usual belief). Some cases need increased rest both before and after meals. (Yet one of the most striking features of the disease is the fact that when urgency drives, the patients prove capable of exertion, both mental and physical, over long periods of time, only, when the emergency has passed, to relapse completely.)

There is one point over which I end in a query. Some patients, in whom the symptoms have become "fixed" by over-treatment, are invalids to the end. But what happens ultimately to the average case? Only the general practitioner is able to tell us that; but I suspect that age brings a cure. Does the Olympic perspective and serenity of mellow years indeed smooth out the worries and perplexities? I should like to know.

PAIN AS A NEUROLOGICAL SYMPTOM AND ITS TREATMENT

(DR. H. A. DUNLOP)

SPECIAL attention is given to the position and character of the pain and its relation to bodily acts, such as movement or coughing. Pain may be due to stimulation of any part of the pathway which, beginning at the periphery and decussating in the neighbourhood of the central canal of the cord, is gathered into the spinothalamic tract and so transmitted to the thalamus. It is believed that the thalamus acts not only as a relaying station for the cortex cerebri, but also in virtue of its mesial and anterior nuclei—the so-called essential organ of the thalamus—enables protopathic sensation, including pain, to enter consciousness. Isolation of the thalamus may cause pain by release from the "damping" influence of the cortex. We must, however, beware of geographical concepts of consciousness. Pain may also be psychogenic; the mechanism of this variety is obscure but is bound up with memory and repression. Psychogenic pain is diagnosed by its unusual distribution, is apt to be "laid on with a shovel," and is unaccompanied by signs of organic disease; a talk with the patient will often reveal the discords and fears of his mind.

Apart from psychogenic pain, the following clinical groups are noted:—

1. *The neuralgias*.—(a) Trigeminal neuralgia is diagnosed by the type and distribution of the pain

which involves the territory of one or more divisions of the trigeminal nerve, usually the mandibular. The severity varies from mildness to agony. The pain is twofold: dull and continuous, and sharp and piercing. The tender spots of Valleix are found over the points where the branches of the nerve become superficial. If the third division is affected, there is unilateral furring of the tongue. The corneal reflex is normal. The skin is left tender after a paroxysm, during which reflex lacrymation, salivation, and spasm of the face (*tic douloureux*) may occur. Referred pain from the teeth must be excluded, but there is no need to sacrifice normal teeth. Analgesics are prescribed, such as aspirin and phenacetin. Gelsemium is useful. It should be borne in mind that amidopyrin carries a definite risk of producing agranulocytosis, and should therefore be reserved only for severe cases of trigeminal neuralgia.

Injection of the Gasserian ganglion usually gives relief for a year or two. In some cases operation needs consideration.

(b) Postherpetic neuralgia may be severe in old people. The scars of herpes zoster are found. The usual analgesics are tried. Massage aggravates the pain. X irradiation is of value in some cases. In a very old subject, opium may be justifiably prescribed. The pain of herpes prior to the eruption may cause great diagnostic difficulty and should always be borne in mind in cases of unexplained pain.

2. *Neuritis*.—I shall say nothing of polyneuritis, but confine my remarks to interstitial neuritis as exemplified by true sciatica. In this condition there is a slight general wasting of the limb; there may be fibrillation of the calf muscles. The ankle-jerk is diminished or lost, but the knee-jerk is brisk. Lasègue's sign is present. The nerve trunk is tender because the inflammation involves the *nervi nervorum*. The pain extends from hip to heel, and antecedent lumbago is the rule. Always do a rectal examination in a case of sciatica and examine the spine and hip-joint, X raying them if necessary. Examine the breasts for cancer.

In the treatment, in addition to counter-irritation, rest, and analgesics, we must mention subcutaneous oxygen injection—this is useful and for the most part safe, although I believe fatalities have occurred from air embolism. In a truncular sciatica, injection of physiological saline in the region of the nerve trunk is of value; while in a radiculitis epidural injection of saline with novocain and manipulation of the spine may help.

3. *Root pains* are referred to a segmental cutaneous area. They are aggravated by sneezing and coughing, which raise the pressure of the cerebro-spinal fluid. A patient recently with a root pain in the territory of the second lumbar segment (upper part of front of thigh) said her limb "went mad" with the pain. Root pains are recognised by the following: (a) there may be blunting of sensation in their distribution (*anæsthesia dolorosa*); (b) root palsies may occur—for example, wasting of an intercostal space, or loss of power in a group of limb muscles; (c) there may be signs of compression of the motor and sensory tracts in the cord and alteration in the reflexes. We look for signs of caries, growth, aneurysm, and lues. The cerebro-spinal fluid may show an increase in albumin. In women the breasts, in men the prostate should be examined for signs of cancer. Primary growths may be operable. Secondary deposits are best treated by deep X ray therapy; morphia should not be too long withheld but supplemented by aspirin, &c. In a few cases chordotomy is

justifiable; either the inferior sensory decussation may be divided along a few segments or the spino-thalamic tract severed. Remember that spondylitis deformans may cause root symptoms.

4. *Lightning pains* vary greatly in intensity. They occur in bouts and may be momentary single pains, or follow each other like machine-gun fire. The bout lasts up to a few days or weeks. The site varies from day to day, or even from moment to moment. Cases with lightning pains frequently have fixed pains, such as girdle pains, as well. Lightning pains occur in tabes dorsalis and in subacute combined degeneration of the spinal cord. In the latter condition, paræsthesiæ are often more troublesome than pain. In tabes, mercury and potassium iodide should be given and later a course of neosarsphenamine (N.A.B.); it must be remembered that this last may aggravate the pains for a time. Salvarsanised serum is apt to aggravate the pain. The usual analgesics should be tried, but the use of morphia is generally inadvisable, because of habit-formation. In subacute combined degeneration, intensive liver treatment is of value.

5. *Central pain* is best exemplified by the thalamic syndrome of Dejerine and Roussey. In this there are spontaneous movements of the contralateral side to the lesion, varying in type—tremor, chorea, or athetosis; dissociated hemianæsthesia; and sometimes constant pain. Unpleasant stimuli may cause intense distress; less commonly, agreeable stimuli excite unusual pleasure. In practice the pain of hemiplegia dolorosa of this type is extremely intractable; whereas, the arthritic joint pains of a hemiplegic respond to the ordinary remedies. Central pain, the source of which is the spinal cord, occurs in some cases of syringomyelia.

6. *Headache*.—All I shall say about this is that if we use the ophthalmoscope in all cases of headache we shall escape many diagnostic humiliations.

7. *Pain in the back* occurs in certain cases of meningitis; the theca is supplied by the nerves of recurrent sensibility. In some cases of acute anterior poliomyelitis in the preparalytic stage active flexion of the spine is intolerable. This may be due to the painful state of the back muscles or of the meninges. Intense muscular pain may occur in the abdomen in this disease mimicking appendicitis or in the limbs simulating osteomyelitis.

8. Lastly, *aching in the limbs* may occur in conditions of muscular rigidity, notably paralysis agitans.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The following all-day courses are to be given: gynaecology at the Chelsea Hospital for Women (Oct. 21st to Nov. 2nd); neurology at the West End Hospital for Nervous Diseases (Oct. 21st to 26th); chest diseases at Victoria Park Hospital (Oct. 28th to Nov. 2nd); urology at St. Peter's Hospital (Nov. 4th to 16th); medicine, surgery, and gynaecology at the Royal Waterloo Hospital (Nov. 11th to 23rd). Week-end courses will also be given as follows: physical medicine at the St. John Clinic and Institute of Physical Medicine (Oct. 26th and 27th); clinical surgery at the Royal Albert Dock Hospital (Nov. 2nd and 3rd); gynaecology at the Samaritan Hospital (Nov. 16th and 17th). In the series of lectures on modern gynaecology held at the Medical Society of London Dr. P. M. F. Bishop will speak on hormone therapy in gynaecology on Oct. 31st, and Dr. Norman Haire on practical contraception on Nov. 7th. Courses and lectures are open only to members and associates of the fellowship. The arrangements for this week will be found in our Medical Diary. Further information may be had from the secretary of the Fellowship, 1, Wimpole-street, London, W. 1.

OPENING OF THE MEDICAL SCHOOLS

On Oct. 11th Sir Walter Langdon-Brown spoke to the medical students of the University of Birmingham at the opening of their winter session. The following is part of his address.

FEAR AND PAIN

BY SIR WALTER LANGDON-BROWN, M.D., F.R.C.P.

EMERITUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE

I WANT, if I can, to point out certain reasons, partly based indeed upon laboratory investigations, why recognition of the patient's individuality positively influences the results of treatment.

It always strikes me as curious that the most materialistic age of medicine—the end of the nineteenth century—was the most sceptical as to the effect of drugs. The discovery of hormones and vitamins did much to overcome this, for if the body was dependent on such chemical substances, it was reasonable to conclude that it would be influenced by other chemical agents. If the body can be affected by a fraction of a milligramme of a hormone or vitamin, it no longer seemed absurd to expect a dose of 5 grains of some drug to do so. But recent work has thrown an interesting new light on the mode of action of drugs which is germane to my thesis. We have long been familiar with the fact that a nervous stimulus can liberate a chemical substance from a gland; we now know, largely because of the work of Loewi and of Sir Henry Dale, that all nervous stimuli act by liberating a chemical substance, either acetylcholine or adrenaline, at their terminals. Moreover it has been shown that the substance, whatever it may be, on which those terminals act can be made either more receptive or non-receptive by drugs. It seems to me that the pharmacology of the future will have to interest itself more and more in the natural history of these receptive substances. All the time new facts are accumulating along these lines. Thus we know that thyroxin and adrenaline may be poured out in response to an emotional state, and Zondek maintains that barbiturates, for instance, may so alter the surface tension of a cell as to bar the way to the admission of thyroxin. Norman Myers has shown also that certain drugs can bar the way to the admission of bacterial toxins. Clearly a large field for research is opening out before our eyes.

Now we may assert that the two things which bring a patient to the doctor are fear and pain. These may coexist in very varying proportions. The unknown is a very potent factor in exciting fear. It is extraordinary to see the way in which a definite diagnosis, even if not an entirely favourable one, may relieve the patient's mind. Pain, even severe pain, may not be accompanied by fear if the cause is known. But under certain conditions pain may be accompanied by a sense of impending dissolution, which excites the most distressing fears, the "angor animi" of the ancient writers. This is not confined to dangerous conditions like angina pectoris, it may occur in the so-called vaso-vagal attacks. A somewhat similar state is sometimes evoked even by an overdose of insulin.

What is the genesis of fear? Fear is the exaggeration and sometimes the perversion of that alertness to the presence of danger which is such a valuable defensive mechanism. They are both expressed

through the same agency—the sympathetic nervous system, which mobilises the body for either fight or flight. Fright may accompany either of these responses, or may be the only response. Fear may be detached from its external motor response, but the internal manifestations may continue. Fear, whether of magic, evil spirits or the dark, panic fear dominated primitive man, and whenever our resistance is lowered by disease, by shock or by psychic conflict, we betray our ancestry, and that strange primitive being which lurks in the unconscious mind of us all peeps out. Every patient, whether he is clearly nervous or bluffs it out, comes to us in a state of fear. The degree of that fear will naturally vary greatly with the individual. The brave man dies but once, it is said, but so does the unimaginative one! Doctors notoriously make bad patients, because their imagination is aroused by the knowledge of so many possible complications and consequences. But I am profoundly sorry for the neurotic; he dies many deaths.

It is clear from what I said earlier that the activation of the sympathetic through fear must modify the response of the patient to the action of the drugs you give. Clearly it is the duty of the doctor to allay fear as much as possible; even more clearly he must avoid exciting fear to the best of his ability. He must always remember that the patient is more receptive to an unfavourable than to a favourable suggestion as to his health. If he fails in these respects, he will interfere with the success of his own treatment and cause unnecessary suffering.

And now as to pain. Physiologically speaking, what are the characteristic features of the transmission of pain? Other sensations have their special receptive end-organs, which are very responsive to their own particular sensation, and have a high discriminative capacity. But sufficiently strong stimulation of any sensory nerve will cause pain and naked nerve-endings only appear to be able to carry painful sensations. The sensation of pain is not so easily elicited but once it is aroused it is explosive in character and prolonged. To illustrate this from a familiar fact. At the right temperature water will give merely a pleasant sensation of warmth, but if you put your hand in water that is just too hot, the painful sensation comes perceptibly later than that of warmth. You may be able to bear the immersion of the hand, but if you increase the stimulated area by plunging in the whole arm, the number of painful impressions will mount up unbearably. Moreover, the pain will persist after you have withdrawn your arm. As we know, these painful sensations pass by their own special tract in the spinal cord, and at a special rate. They arrive at the thalamus which is the older, more primitive receptive structure than the sensory cortex, which enables attention to be concentrated on any part of the body that is stimulated. The sensations received there are also brought into relation with other sensory processes, past and present. The sensory cortex in fact contributes towards a control over feelings. It is by means of this cortical control over attention that a wounded soldier may feel no pain during the excitement of battle, or the hysterical patient experience nothing from the prick of a pin.

That pain, like fear, is a defensive mechanism is obvious. Indeed it is one of the highest value. I remember reading a tale when I was a child of a woodcutter who was promised by a fairy godmother

that one wish should be fulfilled. Smarting from a recent wound from his axe, he wished that he should not feel pain. In a short time he had cut and burnt himself so severely that he died. I always imagine that this story must have been based on a case of syringomyelia. Years ago a philosophic surgeon, James Hilton, wrote a medical classic entitled "Rest and Pain," stressing the value of pain as ensuring rest. The late Sir James Mackenzie also pointed out the value of cardiac pain in preventing over-exertion for a damaged heart. But unfortunately pain, as I have already said, may persist after its value as a warning signal is past. Pain then becomes a portent of a distressing kind.

Both fear and pain present difficulties to the doctor which are all the greater because there is no objective standard by which to measure them. Dilatation of the pupil, acceleration of the pulse, and even the galvano-psychic reflex are not really adequate to do so. The personal factor is enormous. Lombroso maintained that habitual criminals, particularly those who are addicted to crimes of great violence and brutality, have a marked degree of indifference to pain in themselves. In this matter extremes meet, for highly sensitive mystics and martyrs may in their state of spiritual exaltation show a similar indifference to pain. H. G. Wells in "The Research Magnificent" has a pertinent observation on this point. He makes one of his characters remark: "We exaggerate the range of pain as if it were limitless. We think . . . that it passes into agony and so beyond endurance to destruction. It probably does nothing of the kind. . . . The recorded behaviour of martyrs or the self-torture of Hindoo ascetics, of the defiance of Red Indian prisoners; . . . are they really horrible at all? Is it possible that these charred and slashed and splintered persons, these Indians hanging from hooks, have had glimpses through great windows that were worth the price they paid for them?"

Here we touch the fringe of a psychological mystery. It may be that to-day we tend to undervalue the spiritual exaltation that may accompany pain, as much as it seems to us to have been overvalued in the past. A distinguished colleague of mine, Prof. C. E. Raven, has put on record a terribly poignant account of his sufferings from a painful accident but he bears witness to the extraordinary exaltation which accompanied it. But I think he is of the stuff of which martyrs were made and I doubt whether to-day many of us would submit to torture over the theological differences between "homoseion" and "homoioseion" as many did in the past with apparent gladness. It may well be that analgesics and anesthetics have, by abolishing so much pain, made us more sensitive to what remains. To most of us the sufferings endured in the past seem frankly intolerable. But I note a tendency of some modern moralists, such as Hugh Walpole and Cowper Powys, to dwell on the psychological concomitants of pain with undisguised gusto. I must say I do not like that attitude; the frontiers of sadism are soon crossed.

For despite all that poets and moralists have written, and all that martyrs and mystics have endured, pain appears to the medical man to be an evil. He sees many more characters deteriorated than elevated by prolonged pain. I have read with deep sympathy the graphic and courageous account by a surgical friend of his unbearable sufferings from the agonies of thrombarteritis obliterans, but I note that it was when the pain was relieved by amputation that he was able to acquire a gracious

and philosophical calm. Indeed Schopenhauer rated the cessation of pain as one of the few positive pleasures in this world. It may well be that it is just because I have experienced singularly little pain in my life that I regard it as an evil. But it is one of the curious facts about pain that it is usually speedily forgotten, which hardly argues that it is a good thing. Anyhow we are called upon to relieve it, and relieve it we must if we can. It is not for us of all people to argue as to its possible benefits.

And here we are up against another difficulty. Hippocrates, the father of medicine, said "of simultaneous pain in two places, the lesser is obliterated by the greater." Which is greater, physical or mental pain? Few would doubt that the latter is worse. Certainly medical men are constantly seeing instances where patients seek a physical pain as the relief to mental pain. For the former can be talked about and will excite sympathy, the latter they prefer to bury in their own bosoms. And then comes the magician, offering new lamps for old, new pains for old, and pains that can be talked about. In our work we must be constantly on the watch for these substitute pains and search for the underlying mental or emotional cause. An instance comes to my mind of a young lady in the early twenties who suffered according to her own account from excruciating abdominal pains. But she firmly refused to have the cause of these pains investigated by any modern method. Then her father died and left her well enough off to be independent. She rose from her bed of suffering, quarrelled with her mother, and ran away with the married chauffeur to live happy, if not ever after, at any rate up to date! By concentrating sufficient attention on any part of our anatomy we can develop a pain there, and it is all the easier to have a somatic pain if at the same time the emotional sympathetic nervous system is keyed up. I imagine that the stigmata of saints, if not self-produced, were self-induced in some such way.

Clearly it is psychotherapy and not drugs that are called for in cases of substitute pains. But in the cases of physical pain it is clear that the psychological factor also enters into treatment. To come back to my starting point, it is evident that the state of the emotions can very definitely influence the action of the drugs we employ. And herein we find the scientific explanation of the fact that hope is the best of tonics.

WELFARE OF CRIPPLES AND INVALID CHILDREN.—

A conference on this subject is to be held in London on Nov. 7th and 8th by the Invalid Children's Aid Association and the Central Council for the Care of Cripples. After Sir Kingsley Wood, the Minister of Health, has given an opening address on the Thursday morning there is to be a discussion on infectious diseases and their after-effects and on immunisation and other measures that can be taken against them. This will be opened by Sir John Broadbent, Surgeon-Captain S. F. Dudley, Dr. J. Alison Glover, Dr. Matthew Burn, and Dr. W. J. Pearson. Thursday afternoon's meeting will consider the problem of physical handicap in modern life, while the whole of the next day will be devoted to the after-effects of accidents and rehabilitation therefrom. The speakers at Friday's discussions will include Dr. H. C. Carr, Dr. Elizabeth Casson, Mr. S. A. S. Malkin, Dr. Gynecology-Moore, and Mr. D. C. Norris. The conference on practical the Drapers' Hall, Throgmorton-street, and lectures are learn that a certain number of complimentary fellowship. the first meeting will be issued to men and v found in our in practice. Application should be made y be had from Invalid Children's Aid Association, 117, Pimpole-street,

PUBLIC HEALTH

On the State of the Public Health

THE first annual report¹ of the chief medical officer of the Ministry of Health to be issued over the name of Dr. Arthur MacNalty follows its 15 predecessors closely in form and arrangement. The work recorded in it was done under Sir George Newman, to whom graceful tribute is paid by his successor. The first section, which is an innovation, describes the functions and organisation of the Ministry itself. Then follow the essential vital-statistics tables. The birth-rate shows a rise of 0.4 per 1000 over the 1933 figure, which was the lowest on record. Coincident with this there was a fall in the death-rate of 0.5 per 1000. It is noted with justifiable satisfaction that the infant mortality-rate reached the record low figure of 59 per 1000 births. Death-rates for certain areas of County Durham for the years 1930-34 are given, with a summary of the findings of the commission which investigated the allegation that there had been a substantial and progressive deterioration of the public health in these distressed areas. Dr. MacNalty remarks that the evidence contained in this report, evidence which is congruent with much other information available to the medical department, shows that even in the most distressed areas of the country the measures taken by public authorities and the generous efforts of individuals have, so far as the usual indices of health can be trusted, largely held in check the deleterious influences of unemployment and reduced income. At the same time, he adds, the report gives no grounds for complacency. No inquiry can accurately evaluate the grave indirect dangers to health of mind and body which prolonged unemployment involves, and the Ministry is closely watching the position.

GENERAL EPIDEMIOLOGY

The almost complete freedom from small-pox and the lessened incidence of all infectious diseases except scarlet fever and diphtheria are welcome facts. The satisfactory progress made in efforts to produce a bacteria-free vaccine lymph from the chorio-allantoic membrane of chick embryos is recorded. Details are given of five cases of acute nervous disease following vaccination, and it would have been interesting to know the total number of primary vaccinations performed on children of school age and adolescents.

There were 20,000 more cases of scarlet fever than in 1933. Reference is made to the growing realisation that scarlet fever is only one manifestation of the hæmolytic streptococcus, others being tonsillitis and puerperal fever. The question of return cases is discussed; more stress might perhaps be laid on the part played by antitoxin in expediting cure and, by discharge from hospital in the fourth week, in lessening the risks of cross-infection. The public should know that the occurrence of cross-infection or a return case is not evidence of neglect and that discharge of an uncomplicated case in the fourth week is good practice.

Diphtheria incidence was up by over 21,000 cases, the fatality-rate being 5.9 as against 5.5 in 1933. It is pointed out that diphtheria is a personal disease and that wide fluctuations of incidence are to be expected; further, that the rise in the fatality-rate may be due to the inclusion of a smaller number of mild cases than in previous years. Here again the rise might be given; there is no uniformity

of practice, and as long as cases with no clinical manifestations of the disease are admitted as diphtheria patients to some hospitals and not to others comparative statistics will continue to be valueless. The proved variation in virulence of different types of bacillus is referred to. No definite opinion is expressed on the value of immunisation. The public would appreciate a dispassionate verdict on this, perhaps the most vital public health problem of the day.

Practitioners will read with interest the account of the incidence of leptospirosis (Weil's disease) in those whose work entails contact with water open to contamination by the urine of rats.

MATERNITY AND CHILD WELFARE

The general improvement in the services is reported and tribute is paid to the efforts of public health authorities, practitioners, medical officers, and midwives to reduce the persistently high maternal mortality-rate. A summary of the various steps taken or suggested by the Ministry is given, together with a list of the county boroughs in which conditions are being specially investigated on account of the high average-rate obtaining over a period of years. We would suggest special reference to towns where improvement has been made; nothing is more calculated to discourage an authority than to continue to include it in the "black list" on account of its ten-year average when it has already effected substantial reductions. The value of coöperation between practitioners and the medical officer of health is stressed: without such coöperation no permanent improvement can be expected. The value of reasonable publicity and propaganda is admitted. Reference is made to the unsatisfactory position of the average midwife at the present time and sympathetic mention is made of proposals under consideration for a full-time midwifery service.

TUBERCLE—V.D.—CANCER

There is nothing startling in the section devoted to tuberculosis. The after history of cases, problems of employment, the infection of home contacts, the effect of housing conditions are among the subjects discussed. Appreciative reference is made to improvement in the equipment of dispensaries particularly as regards facilities for X ray examination and to the cordial relations existing between practitioners and tuberculosis officers.

Much of the section on venereal diseases deals with the comparative value of ad-hoc and other types of treatment centre. It appears that the fear that transfer of the centre from a voluntary hospital to a municipal clinic would lessen efficiency has proved groundless; in most cases, indeed, the reverse, shown by an increase in attendances, has been the case. No reference is made to a problem which would appear to require immediate central investigation—viz., the risk run by road transport workers through the development of a new profession; that of the travelling prostitute. Presumably the matter is being investigated.

There is no improvement to record in the incidence of, or mortality from, cancer, although hope is expressed that a peak of mortality will shortly be reached. An extremely valuable table of deaths arranged according to the site of the lesion is given and a statement on the progress of research and on the work of the Radium Commission is made.

¹ H.M. Stationery Office. 3s.

Other sections deal with nutrition, milk-supplies, food standards, food poisoning, and appropriation of hospitals under the Local Government Act—all matters of first-rate importance.

In concluding this brief review we commend to the deliberate study of every medical man and woman Dr. MacNalty's first report. It deals with many controversial matters and will be quoted widely in the lay press. On some of these an authoritative pronouncement from the chief medical officer would be welcomed, not only by the profession but by the public. The reputation of the Ministry of Health stands high with the people of this country, and the report might perhaps go further in tendering advice about matters on which there is now much misguided and contradictory publicity.

Pneumonia and the M.O.H.

Acute primary pneumonia, together with acute influenzal pneumonia, became compulsorily notifiable by medical practitioners in 1919. A memorandum which was issued at the time by the Local Government Board has now been reissued in a revised form by the Ministry of Health. It was never anticipated that in the present state of our knowledge the mere notification of pneumonia and the action consequent thereon would result in any great immediate reduction in the total incidence of the disease, but it was thought that the public might thereby be awakened to a sense of the gravity of the malady. It was thought, too, that notification might supply valuable statistical information as to the distribution of pneumonia, and contribute in some measure to a reduction in the mortality from it, by bringing to light those cases in which the local authority could help by providing nursing or other assistance or by arranging for institutional treatment.

It may be frankly stated that on the experience of the last 15 years there appears to be little evidence that the notification of pneumonia serves a useful purpose. The majority of medical officers of health receive the notifications and spend the minimum of time on inquiries. None the less it is still the statutory duty of the medical officer of health, following notification, to "make such inquiries and to take such steps as are necessary or desirable for investigating the source of infection, for preventing the spread of infection and for removing conditions favourable to infection." In practice attention will be more usefully directed to patients notified from the poorer streets and it may be found that skilled nursing is urgently required. Such nursing may be provided in various ways—e.g., by arrangement with a district nursing association or through the poor-law domiciliary service. In any case the nurse works under the instructions of the private practitioner or the district medical officer, as the case may be. Since the disturbance of a pneumonia patient involves special risk, great care is taken in selecting cases for treatment in hospital; regard is had to the sanitary condition of the home, the possibility of isolation, and the means and facilities for home nursing and general care. In some cases, however, removal to hospital may be the patient's only hope of recovery.

The pneumonia patient freely disseminates virulent pneumococci by droplets. Persons attending the patient do not appear to be subject to much risk of infection, but it is likely that they may become carriers and pass the infection on to others more susceptible. The patient is therefore isolated so far as is practicable. In a hospital ward the patient's bed should be separated from others by screening.

The sputum and the discharges from the nose should be carefully disposed of. Handkerchiefs should be boiled or (if of paper) burnt. Attendants on a pneumonia patient should observe the ordinary precautions necessary in dealing with infectious disease. The memorandum advises prophylactic gargling and gentle douching of the nose, but recommends the use of face-masks only in cases of influenzal pneumonia.

The local authority should provide facilities for the bacteriological examination of sputum and the typing of the organism. There is no evidence that the pneumococcus can survive for long outside the body and special disinfection of bedding or rooms is therefore unnecessary. When visiting a notified patient the opportunity is taken to deal with any obvious defect in sanitation which may be found.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 5TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2464; diphtheria, 1199; enteric fever, 37; acute pneumonia (primary or influenzal), 499; puerperal fever, 37; puerperal pyrexia, 114; cerebro-spinal fever, 11; acute poliomyelitis, 22; acute polio-encephalitis, 3; encephalitis lethargica, 6; relapsing fever, 1 (Widnes); continued fever, 1 (Battersea); dysentery, 23; ophthalmia neonatorum, 102. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Oct. 11th was 2803, which included: Scarlet fever, 944; diphtheria, 1119; measles, 23; whooping-cough, 288; puerperal fever, 17 mothers (plus 9 babies); encephalitis lethargica, 268; poliomyelitis, 16. At St. Margaret's Hospital there were 21 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 2 (0) from measles, 5 (1) from scarlet fever, 8 (3) from whooping-cough, 25 (1) from diphtheria, 45 (10) from diarrhoea and enteritis under two years, and 25 (0) from influenza. The figures in parentheses are those for London itself.

The only death from enteric fever occurred at Birmingham. Fatal cases of diarrhoea and enteritis were distributed over 25 great towns, the highest number being Hull 4, Nottingham and West Bromwich each 3, no other great town more than 2. Liverpool reported 2 deaths from measles, Manchester 2 deaths from scarlet fever, and Leeds 3 deaths from whooping-cough. Fatal cases of diphtheria occurred in 22 great towns, 2 each being reported from Southampton, Oldham, and Sheffield.

The number of stillbirths notified during the week was 272 (corresponding to a rate of 45 per 1000 total births), including 29 in London.

MANFIELD ORTHOPÆDIC HOSPITAL, NORTHAMPTON. Approved extensions to this hospital will include a new ward for 24 patients, eight single-bed wards for private patients, and more accommodation for the nurses' home. By next spring this institution should have a total of 180 beds; in 1925 it had only 20. The extensions will cost £10,000.

THE HYGIENE OF YOUTH.—A series of lectures on this subject will be given under the joint auspices of the Royal Institute of Public Health and the Institute of Hygiene at 28, Portland-place, on Wednesdays at 3.30 p.m., from Oct. 23rd to Nov. 27th. Dr. Alan Moncrieff will give the first lecture, on the early weeks of life in relation to the health of the adolescent, and the subsequent speakers will be Dr. L. S. T. Burrell (tuberculosis in youth), Dr. Reginald Miller (rheumatism and heart disease in youth), Mr. William Ibbotson (hygiene of breathing, hearing, and speaking), Prof. J. W. H. Eyre (adolescence and microbial infections), and Dr. R. Cove-Smith (pitfalls of physical training). The lectures are open to all.

CORRESPONDENCE

THE ATTITUDE OF SURGERY TO
HÆMATEMESIS*To the Editor of THE LANCET*

SIR,—Mr. Gordon-Taylor concludes his address in your last week's issue with the words "... the golden age of gastric surgery will have been attained only when all cases of hæmorrhage from chronic ulcer come to operation within that space of time"—i.e., the first 48 hours. Some latitude may be allowed for a peroration, but the meaning is that all cases of hæmorrhage from chronic ulcer should be operated upon immediately.

Considerable responsibility is incurred by such a statement, and we are entitled to weigh the evidence produced in its support, especially as Mr. Gordon-Taylor gives no statistics of his own results, and contents himself with quoting from only one writer, Finsterer of Vienna. It will be noted that the statement is applied only to chronic ulcers, implying that the differential diagnosis from an acute ulcer can be made, at least with reasonable certainty, within 48 hours, including cases in collapse following hæmorrhage. With regard to the risk to life from ulcer hæmorrhages, Conybeare's figure of 2.5 per cent. mortality is commonly quoted, and there is no doubt that if all cases of hæmorrhage however trivial are included, the case-mortality is very low and is somewhere in this neighbourhood. But in the last decade statistics have gradually pointed to the existence of a serious group which includes nearly all the fatalities. Credit is due to Bulmer as being the first to indicate the existence of such a group when he studied the mortality in cases admitted expressly for hæmatemesis and found a mortality of 10 per cent. in 1927 and 16 per cent. in 1931. The separation of a severe group has been further advanced by the statistics of Aitken at the London Hospital and Lloyd Davies and Nevlin at St. Thomas's Hospital. Stated shortly, the latter writers used a criterion of below 20 per cent. of hæmoglobin, and thus separated a group in which the mortality was about 45 per cent., while the mortality of the remaining cases was 6 per cent., although all these had been admitted expressly for hæmatemesis or melæna. It is thus clear that there is a serious group in which there is a very high mortality, while outside this the mortality is low, although the hæmorrhage may be considerable.

Mr. Gordon-Taylor places considerable reliance on the views and statistics of Finsterer. The general outlook of this surgeon may be illustrated by two sentences which are quoted "Any hæmorrhage from an ulcer is almost as urgent as a perforation," "Bleeding from a chronic ulcer is an imperative indication for immediate surgery." Finsterer gives a table of his results of "immediate operation" on cases of hæmorrhage from an ulcer. He states that he only includes cases beginning with a massive hæmorrhage or with melæna with syncope, more trivial hæmorrhages being excluded. In these circumstances he performed gastrectomy within 48 hours in 39 cases, with one death, a mortality-rate of 2.5 per cent., the only death being in a man over 80 years of age. He concludes his article with the following statement: "Performed in suitable surroundings, 'operation for acute hæmorrhage gives the same good results as operation for non-bleeding ulcer.'" Such a statement is manifestly absurd, and a study of Finsterer's original article gives the impression of the same exaggeration throughout. Neither his statements

nor his statistics can be safely accepted nor deductions drawn from them.

The treatment of hæmorrhage will not be improved by these means. It does not assist to make sweeping statements that all cases of hæmorrhage must be treated surgically or treated medically. What we need to do is to distinguish those cases which should be treated medically, and those which should be treated surgically. May I return to the serious group in which the fatalities occur? It is not easy to give a clinical description of this group, but, as Aitken says, it is not difficult to recognise it clinically and to recognise if an individual case comes within it. Can we go further and decide whether an individual case in this group will live or die under medical treatment? Aitken says that we cannot do so at present, and my experience agrees with this. We must most of us have seen a desperate case recover on which a surgeon was unwilling to operate.

So far as the treatment of severe hæmorrhage is concerned, it is to this group that we need to pay attention. We do not know which cases will recover, and we do not know which should be operated upon and which should be treated medically, and so far as I am aware there are no statistics which are of assistance in comparing the results of medical and surgical treatment. Perhaps it may be possible for surgeons with an extensive experience to find from their records statistics bearing on this group, which can be compared with statistics of medical treatment. In the meantime, in fairness to our patients, we must decide the treatment of each case individually, with an open mind and with the coöperation of medical and surgical acumen.

I am, Sir, yours faithfully,
Devonshire-place, W., Oct. 12th. H. LETHEBY TIDY.

PROTEOLYTIC ENZYMES IN CANCER

To the Editor of THE LANCET

SIR,—In the *Journal* of the Canadian Medical Association for October, 1935 (p. 364), an article entitled "The Study and Treatment of Cancer by Proteolytic Enzymes" by Dr. H. C. Connell appears. In this article reference is made to the fact that the Imperial Cancer Research Fund had been asked by Dr. Connell to investigate experimentally his claim to have discovered a method of killing cancer cells in vivo—potentially a cure for cancer. We have prepared from mouse tumours, in accordance with directions received, the solutions which Dr. Connell calls "ensols" and have tested these "ensols" on the appropriate tumours of mice. In no case has the growth of a tumour been checked or affected in any way.

I am, Sir, yours faithfully,
W. E. GYE.
Imperial Cancer Research Fund, Queen-square,
London, W.C., Oct. 14th.

PLASTER TECHNIQUE IN TREATMENT OF
FRACTURES*To the Editor of THE LANCET*

SIR,—I have read with great interest your leading article of Sept. 28th on plaster-of-Paris, and I trust you will allow me to make a few comments, which are thus belated, because I was in Vienna when the article appeared. While every orthopaedic surgeon will agree with the main points of the article, yet I feel anxious lest the impression it will make on the rank and file of the profession may be an unfortunate

one; so that, like many another piece of propaganda, it may precipitate the very evil which it is intended to prevent. Thus:

1. Although the article states that good plaster work "still remains an exacting art, demanding not only some experience and natural aptitude . . ." yet the implication is that nearly all members of the profession ought to dabble in this art, disregarding the fact, which many of us know too well, that in the hands of the inexpert plaster often has disastrous effects—far more disastrous than those of stock-splints badly applied.

2. Another implication is that plaster should replace all other types of splint. Now for such conditions as wrist-drop the light vulcanite splint is incomparably better; while there is agreement among the majority of orthopaedic surgeons that plaster-of-Paris should only play a minor part in the treatment of scoliosis and many other spine conditions.

3. As regards technique: (a) only the advantages and none of the drawbacks of the *proprietary bandage* (celluloid-plaster) are referred to. It is noteworthy that Böhler uses only the condemned "hand-made" bandage; (b) the suggestion is made that the *padded plaster* has no place in surgery, but the present writer is convinced from a study in orthopaedic clinics all over the world, as well as from long practical experience, that such a statement shows an utter lack of conception of the possibilities of plaster-of-Paris. It is the badly padded plaster that should be condemned; the unpadded is equally detrimental in an unsuitable case.

4. Finally, in regard to Böhler's contribution to the solution of the fracture problem, I feel convinced from two weeks' recent study in his clinic that the profession will be misled if it is induced to believe that any widespread improvement in plaster technique will result in a corresponding improvement in the results of fracture treatment, however earnestly such progress may be desired by the profession and by the public. Böhler's plaster technique has serious rivals in U.S.A., France, and Italy (and let us not forget our own war-surgeons), but the organisation of his clinic has certain other features, which I feel convinced play at least equal parts in producing his admirable results. These are: (a) A team with a very experienced, as well as brilliant, surgeon at the apex of the pyramid and also fairly senior full-time surgeons carrying out the treatment under his direct supervision—what many British practitioners might characterise as a "fascist organisation," or a "one-man show." (b) A system of records and frequent attendances, reinforced by the financial weapon of insurance, which secures most detailed and continuous supervision of each patient until he is able to resume his place in the working community. (c) The provision of sufficient beds to allow a short period of *in-patient* treatment for every injury of joint, tendon, or tendon-sheath, even in the upper limb; also periods of from two to six months for all leg and thigh fractures. Pott's fractures with any swelling are given in-patient treatment with the limb raised and no plaster till the skin and circulation are recovered. (d) Finally, an expenditure on X rays, which would be regarded as grossly extravagant by most British voluntary hospital boards. It is this frequent and regular control by X rays of the position of the fragments which results in the early recognition of recurrent displacement, while there is still time to correct it; for even the unpadded plaster allows slipping in certain cases.

The limits of a letter do not allow for any thorough review of this wide and most important subject, but I trust that your courtesy in allowing me to trespass on your space to this extent may induce many of your readers to give careful thought to the above points, which are only some of the many deserving consideration.

I am, Sir, yours faithfully,

M. FORRESTER-BROWN.

Queen-square, Bath, Oct. 13th.

ORIGIN OF BOILS

To the Editor of THE LANCET

SIR,—Dr. Lockhart raises a very interesting question. After prolonged observation I should say that boils on the neck are almost entirely confined to the male, whereas there is a peculiar form of superficial eczematous dermatitis of the nape of the neck almost entirely confined to women. Boils on the neck may be associated with acne of that region or may occur independently. It is perhaps a curious fact that whereas acne is common in both sexes it is rarely found on the neck in women. If one studies the distribution of the hair on the neck it is found that the hair, where it grows low down, is apt to do so in two parallel columns, one on either side of the middle line, and these columns are much more frequently the sites of boils than the middle line. On the other hand, the "nape eczema" of women more frequently affects the middle line.

It would occupy too much of your space to go into the causation of boils from the constitutional side and I therefore confine myself to the local, especially as this is the aspect of Dr. Lockhart's inquiry. I agree that the use of the clippers is associated in some cases with the appearance of folliculitis and boils, but I offer a different explanation. It will be noticed, if attention is paid to the point, that in men who get boils on the neck the hair is coarse and grows low on the neck. Any habitually shaven man knows how uncomfortable his face feels on the pillow after being unshaven for three or four days. The short stiff hair is driven into the skin and worries the follicle. As the hair grows long enough to become flexible this irritation ceases. In the daytime men wear stiff or close-fitting collars which are liable to cause this follicular irritation where the hair is clipped short. They should therefore either allow their neck hair to grow long or shave it with a safety razor daily. For some years now women have had the clippers applied to their necks, yet one rarely if ever sees boils on their necks. I suggest that this is due to the fact that since the clipping has been customary the clothing of the neck has also been less close and rigid.

There remains the "nape eczema" of women. Some years ago I suggested that this might be due to the wearing of furs round the neck. I am here not alluding to dye dermatitis but to the mechanical irritation by the scrubbing of the neck with worn and broken fur. This would naturally produce an irritative dermatitis of superficial type and I have actually seen it produced on the throat in men by the use of a much worn badger shaving brush.

I should like to make it clear that I do not think that a dirty or infected clipper is a matter of no importance, but merely to point out what are I think the main causes of these diseases.

I am, Sir, yours faithfully,

London, W., Oct. 15th.

ARTHUR WHITFIELD.

TREATMENT OF SCABIES

To the Editor of THE LANCET

SIR,—Seeing that Dr. Kingston's excellent article on this subject in THE LANCET of Oct. 12th confirms the experiments which I myself made about 20 years ago, but failed to publish, I feel that I must now support his findings, and congratulate him on drawing attention to the fact that whereas the "sulphur treatment" has been handed down from one text-book to another as a so-called cure for this condition, this is far from being the case as is so commonly thought. The "cure while you wait system," as used in some hospitals, where the patient is given a sulphur bath, thoroughly scrubbed with a nail-brush and sulphur ointment applied, is I am sure doomed to failure. Much may depend upon the efficiency of the scrubbing and thereby opening up the burrows made by the acarus, but it must not be forgotten that if only one of these escapes (and I am convinced that many more than this must do so), and if only one acarus is left behind under the skin, eggs will be produced at the rate of 2 or 3 a day for 14 days. The acarus may lay as many as 50 eggs. These take 14 days to hatch, so that it would take about six weeks before the last eggs are hatched. This surely is the cause of so many recurrences after so-called immediate cures.

My contention is that every case treated should be examined weekly for at least six weeks before one can affirm that a cure has been effected, and yet how seldom is the trouble taken to carry out this routine. In a large hospital, such as a mental hospital, it is practically impossible to eradicate this trouble unless some such routine is adopted.

In support of the findings which Dr. Kingston has recorded I would add that I have found the acarus in a burrow after the patient had had the recognised sulphur bath treatment, followed by daily applications of sulphur ointment for 14 days. I have also found the live acarus in the burrow under the skin of a patient who had had the sulphur bath treatment followed by applications of sulphur ointment twice a week for four weeks, and in many cases after shorter periods of similar treatment. Further, in a wax cell on a slide under a cover-slip I found that the acarus would live for 24 hours immersed in water, 48 hours crawling about over sulphur ointment, and as long as seven days in a cell such as described with nothing else in it.

I am naturally pleased to see that Dr. Kingston has taken the trouble to make somewhat similar investigations and that his results so closely agree with my own. But surely it is time that medical students were taught that the sulphur bath and ointment, as described in most text-books, is not a cure, and that repeated trials and examinations must be made to prevent the relapse and further spread of this condition, which once left unrecognised and improperly dealt with becomes a source of untold trouble in any large institution.

I am, Sir, yours faithfully,

R. EAGER,

Oct. 15th. Medical Superintendent, The Hospital, Exminster.

GERMICIDAL PROPERTIES OF MERCURY PREPARATIONS

To the Editor of THE LANCET

SIR,—In the annotation entitled Skin Disinfection in your last issue (p. 838) you refer to the well-known fact that the germicidal properties of mercury preparations as determined by different methods vary

enormously. We think that the following simple experiments throw a great deal of light on the causes of the discrepancies.

When the carbolic-acid coefficient of mercury preparations is determined, a loopful of the bacterial culture, after contact with a known concentration of the mercury compound, is removed after a known interval of time, and is subcultured into a given quantity of nutrient broth. If no growth subsequently occurs in this broth it has been assumed that the bacteria in the treated culture were killed when the loopful was removed. Usually this assumption is correct, but in the case of mercury preparations the assumption is purely fallacious. The refusal to develop is due to the bacteriostatic action of the accompanying mercury salt carried over with the loopful into the broth. If instead of plain nutrient broth, broth containing 0.2 c.cm. of a sterile 5 per cent. solution of sodium sulphide per 5 c.cm. of broth is employed, an entirely different picture of the facts is obtained. The sulphide inactivates the mercury which is carried over, and the supposedly dead germs are found to be alive and unharmed. The differences between the real and the apparent germicidal properties of a few mercury preparations are seen in the following Table:—

Mercury preparation.	Real carbolic-acid coefficient.	Apparent carbolic coefficient.
Mercuric chloride ..	0.15	800
Mercuric cyanide ..	Less than 0.1	25
Mercuric iodide ..	7	1300

N.B.—The mercuric chloride in the strong solutions that were necessary was dissolved with the help of sodium chloride and the mercuric iodide with the help of potassium iodide. The actual coefficient of mercuric cyanide could not be determined because a 10 per cent. solution (which is actually a supersaturated solution at 18° C.) failed to kill the bacteria after 10 minutes' contact.

We think we can now give a reasonable explanation of the germicidal failures of mercury preparations under clinical conditions. For instance, the Departmental Committee of Maternal Mortality and Morbidity in their final report (1932, p. 113) showed that a 1 in 1000 solution of mercury perchloride did not kill hæmolytic streptococci on the hands nor did it prevent reinfection after a time. From the above table it will be seen that mercury perchloride is actually a much weaker germicide than pure carbolic acid, and a 1 in 1000 solution is a very feeble one bactericidally. When such a solution is applied to the skin, the mercury compound tends to combine slowly with the excretions of the sweat glands to form insoluble compounds, and as the bacteria have not been killed they can subsequently be removed in the living condition. It is only when some soluble uncombined mercury compound is removed with the bacteria that fictitious results are obtained.

The germicidal ineffectiveness of soluble mercury compounds in the presence of pus and blood is too well known to require special comment.

We are, Sir, yours faithfully,

W. C. REYNOLDS,
S. N. H. STOTHART.

Hull, Oct. 15th.

PARIS

(FROM OUR OWN CORRESPONDENT)

THE SURGICAL CONGRESS

THE Association Française de Chirurgie held its forty-fourth congress in Paris from Oct. 7th to 12th, these dates being chosen so that it might coincide with the motor show.

In his opening address, Prof. Gaston Michel, of Nancy, courageously faced the dangers threatening the medical profession at the present time, as much from within as from without. He pleaded for scientific probity, and a critical attitude towards "too beautiful statistics" and towards those who

sacrifice truth for the sake of innovation. He rang the changes on a Pauline aphorism by declaring that intelligence, sang-froid, and skill profit nothing without rectitude: "for a surgeon, one of the surest and most durable elements of success is scrupulous honesty and unflinching morality, both from the surgical and the scientific points of view. Without conscience, science is but the ruin of the soul." Another danger, he said, with which surgery is faced to-day is standardisation. During the war teamwork was necessary, and personalities sometimes had to be sacrificed. But the reign of the team can continue only if it permits of the development of the individual; otherwise, personal responsibility, the factor of greatest importance, will decline. Excessive collectivism will cultivate the spirit of the functionary and will destroy the surgeon's initiative.

Turning to more concrete problems, Prof. Michel referred in no uncertain terms to the surgeons who refuse to operate, even in an emergency, without having been paid their fees, or who undertake unnecessary operations. Surgery is becoming more and more democratised; every year the supply of surgeons increasingly exceeds the demand, and quantity is obtained at the cost of quality. The younger generation is in a hurry, whereas surgery requires "an aristocracy of soul," and an education which includes moral as well as intellectual elements. "The phantom of wealth, to be acquired quickly and no matter how, induces many to neglect education in a moral sense. The moral crisis existing in the medical profession to-day is not so much to be traced to individuals as to the milieu of the moment." Prof. Michel would have his ideal surgeon serve a long and hard apprenticeship in biology, physiology, and experimental surgery as well as in anatomy. "One's memory of anatomy is the first factor in the calm, the sang-froid, the confidence, the regularity, and the precise and perfect execution of the surgical act." But this is not all. A classical education is essential to the development of a mature and critical judgment; and it gives great suppleness to the mind.

In Prof. Michel's opinion, vigilance on the part of the medical profession is required at the present time in connexion with the appointment of surgeons to hospitals in small and provincial communities. In university towns such appointments are made under equitable conditions. But in communities of less importance politics are apt to intrude, and laymen are tempted to impose their opinions and personal inclinations on the community so that it does not always get the best qualified applicant for a hospital appointment. It should always be made after an open competition at which the judges should be surgeons, not lay politicians.

Apart from numberless minor communications, there were three subjects to which the congress paid special attention. The first was infarct of the mesentery on which an opening paper (or rather monograph) was communicated by Dr. André Ameline, of Paris, and Dr. Charles Lefebvre, of Toulouse. They find that the condition is probably commoner than has been thought, and that there is no one pathognomonic sign of it. The most important symptom is pain associated with collapse. The second main subject was fracture of the calcaneus, and the principal speakers were Dr. Fernand Paitre and Dr. Marcel Boppe, both of Paris. The invitation of Dr. L. Böhler, of Vienna, by the organisers of the congress to speak on this subject was a happy inspiration; and much of the opening paper was an advocacy of Böhler's operation for this fracture. In fact,

Dr. Paitre and Dr. Boppe have come to the conclusion that when a fracture of the calcaneus is articular, and the state of the skin about the tenth day after the accident contra-indicates any incision, Böhler's method of orthopædic reduction should be preferred to any open operative procedure. Böhler's method requires great technical precision and most strict post-operative supervision. Whatever be the treatment given, no final result of articular fractures can be expected in much less than a year.

The third main subject was the technique and physiological consequences of operations on the diaphragm, phrenicectomy excepted. The main report was presented by Dr. Henri Costantini, of Algiers, and Dr. G. Ménégaux, of Paris. Among the distinguished foreigners invited to speak on this subject were Prof. Sauerbruch, of Berlin, and Dr. Harrington, of Rochester, U.S.A.

IRELAND

(FROM OUR OWN CORRESPONDENT)

PUBLIC HEALTH ADMINISTRATION IN DUBLIN

SOME weeks ago the Minister for Local Government and Public Health appointed a tribunal to investigate the question of enlarging the boundaries of the City of Dublin and also the financial relations between the several local authorities in the county of Dublin. The chairman of the tribunal is a distinguished lawyer and his two colleagues are officials in the Minister's Department, one an engineer and the other an expert in accountancy. No member of the tribunal has any medical experience or any qualification for forming an opinion on the many matters concerning public health administration with which the tribunal will have to deal. The council of the Irish Medical Association drew the attention of the Minister to this weakness in the tribunal and asked him to add to its personnel one medical member. The council pointed out that the decisions to be made by the tribunal will affect the administration of public health for many years to come, not only as regards the boundaries of administrative areas, but as regards such special questions as the provision and maintenance of an adequate hospital service, water-supply, housing, and town-planning. While the council did not question the capacity of the several members of the tribunal in their own spheres, none of them had the training or experience to fit them to form a useful opinion on such topics. To this suggestion the Minister has found himself unable to accede. There is no doubt that the report of the tribunal will suffer from absence of a member who could give sufficient weight to considerations of public health.

The most interesting evidence yet submitted to the tribunal has been that of Mr. M. Russell, F.R.C.S.I., superintendent medical officer of health for the city of Dublin, who made a clear statement of the present public administration and of the problems which have to be solved in Dublin. He stated that the Census of 1926 showed that there were 25,789 families living in one-room tenements in Dublin, of which 14,725 were of three persons or upwards. There are 2000 cellars in the city occupied as dwellings. The housing problem was most urgent and should be dealt with as rapidly as possible. To meet the needs of the population 2000 houses would have to be built each year, and at present not more than 1000 a year were being built. There is difficulty in finding suitable housing accommodation for those

turned out of insanitary dwellings. These mostly were poor people who could not afford to pay rent. In future fever cases would be treated in one large hospital which would be under the joint control of representatives of the present board of Cork-street Fever Hospital, the corporation of Dublin, and the Dublin county council. It would be built from funds supplied from the Hospitals' Sweepstakes. The maternity services of Dublin are, Mr. Russell says, very satisfactory: for some years there has been no instance of a midwifery case being attended by an untrained or unqualified person. The hospitals in the city were maintained on a voluntary basis, the corporation making annual contributions amounting in all to £6072 a year. Payments were also made to certain hospitals for services in connexion with child welfare, the school medical service, tuberculosis, and venereal disease. The corporation was represented on the management of all the voluntary hospitals in receipt of grants except in two cases. The voluntary system, each hospital being its own master, had worked well, and he never found any difficulty in getting a poor patient into hospital. The relation between the corporation and the hospitals was most friendly and no difficulty ever arose. He did not see any need for a municipal hospital or for reserving a certain number of beds in each hospital. The health of the city was improving, particularly as regards tuberculosis, and infant mortality was diminishing.

There was a public abattoir in Dublin, but there were still 64 private slaughter-houses. Licences were not renewed for these latter on the death of a licensee, as it was very desirable to abolish all slaughter-houses. The total Government grants to the public health department of the city amounted to £31,258, of which £10,336 was for tuberculosis, £4371 for school meals, £7232 for maternity and child welfare work, and £4225 in respect of the treatment of venereal disease.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Capt. A. T. Rivers placed on the Ret. List.
Surg. Comdr. M. Brown to *President* for Medical Dept., temp.

Surg. Comdr. W. H. Murray to *Drake* for R.N. Hospl., Plymouth.

Surg. Lt.-Comdrs. R. R. Baker to *Victory* for R.M. Infirmary, Portsmouth, and C. Keating to *St. Angelo* for R.N. Hospl., Malta.

Surg. Lt. J. W. Oliver to *Pembroke* for R.M. Infirmary, Chatham.

ARMY MEDICAL SERVICES

Maj.-Gen. (Supern.) P. H. Henderson, C.B., D.S.O., late R.A.M.C., K.H.P., and Maj.-Gen. J. F. Martin, C.B., C.M.G., C.B.E., late R.A.M.C., K.H.S., retire on ret. pay.
Col. G. A. D. Harvey, C.M.G., late R.A.M.C., to be Maj.-Gen.

Lt.-Cols. to be Cols.: G. F. Dawson, M.C., from R.A.M.C., and A. C. Hammond Searle, M.C., from R.A.M.C.

The undermentioned relinquish their appts.: Maj.-Gen. P. H. Henderson, C.B., as Dir. of Hygiene, War Office, and Col. A. C. Hammond Searle, M.C., as Asst. Dir. of Hygiene, War Office.

The undermentioned appts. are made: Col. H. H. A. Emerson, D.S.O., late R.A.M.C., to be Dir. of Hygiene, War Office, and Lt.-Col. D. T. Richardson, M.C., R.A.M.C., to be Asst. Dir. of Hygiene, War Office.

ROYAL ARMY MEDICAL CORPS

Majs. to be Lt.-Cols.: H. G. Winter, M.C., and N. Cantlie, M.C.

ROYAL AIR FORCE

Wing Comdr. P. H. Young to No. 11 Flying Training School, Wittering, for duty as Senior Medical Officer.

Squadron Leader C. J. S. O'Malley to Princess Mary's R.A.F. Hospital, Halton, for duty as Medical Officer.

Flight Lts. F. B. C. L. B. Crawford and N. I. Smith are promoted to the rank of Squadron Leader.

Flying Offrs. H. F. Harvey, J. C. Blair, and A. W. Callaghan are promoted to the rank of Flight Lt.

Flight Lt. G. S. Strachan to Central Medical Establishment, London.

DEATHS IN THE SERVICES

Lieut.-Colonel WILLIAM JAMES NIBLOCK, who died on Oct. 10th at Bournemouth, was born in July, 1871, qualified M.B.R.U.I. in 1894, and became F.R.C.S.I. in 1906. He took his first commission in the Indian Medical Service in January, 1896, became major in July, 1907, and rose to be first surgeon and superintendent of the General Hospital, Madras, and principal and professor of surgery in the Medical College, Madras, in 1912. He retired in February, 1923. He was an hon. associate of the Order of St. John of Jerusalem in England.

OBITUARY

SIR FREDERIC CONWAY DWYER, M.D. Dub.

PAST PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS IN IRELAND

Sir Conway Dwyer, who died in Dublin on Oct. 10th, had been in failing health for some time, and had retired from active practice about two years ago. Born in Dublin in 1860, Dwyer received his medical education at Trinity College, Dublin, where he graduated in medicine and surgery in 1883. Within a few years of qualification he was appointed one of the surgeons to Jervis-street Hospital, whence he emigrated some years later to the Meath Hospital, and in 1907 he was appointed surgeon to the Richmond Hospital. In recent years he was chairman of the board of governors of the last-mentioned institution. In 1898 he became a fellow of the Royal College of Surgeons in Ireland, of which he subsequently was vice-president, president, and honorary secretary; he was also

[Photograph by Lafayette

SIR CONWAY DWYER

for some years professor of surgery in its school. During the war Dwyer was operating surgeon at King George V. Hospital in Dublin with the rank of lieutenant-colonel, and he was knighted in 1921. He was inspector of anatomy for Ireland, and also visiting inspector in lunacy; and he took much interest in the Peamount Hospital for Consumption, where he became honorary treasurer and chairman.

For the greater part of a long professional life Sir Conway enjoyed a large consulting and operating practice. His interests in surgery were not limited to one field, and he was an admirable general hospital surgeon. Gifted with abundant common sense and sound judgment, he was painstaking and careful in his work, and was liked both by patients and colleagues for his geniality and kindness. He was unmarried.

PANEL AND CONTRACT PRACTICE

Dangerous Drugs

At the annual conference of the National Association of Clerks to Insurance Committees a discussion on some of the difficult points of medical benefit was initiated by the clerk of the London committee. One is the position of a practitioner who, having been deprived of his authority to possess, to supply, or to prescribe dangerous drugs, applies for admission to the medical list. The practitioner (still a registered practitioner) would have a right to have his name included in the medical list in exactly the same way as any other doctor, but the committee would require him to make an arrangement with another practitioner to deputise for him in any case in which the use of one of the scheduled drugs was necessary. But this would depend on the willingness of another practitioner to work with him.

Conflicting Tribunals

Another matter for discussion emerged from a case which recently arose in which a complaint was made in respect of treatment provided for a deceased insured person, and at the same time an action was started by the father of the deceased girl for the recovery of damages from the practitioner. The medical service subcommittee decided that the case was one of which they could not dispose without a hearing. The solicitors for the complainant and those for the respondent then requested that the hearing should be deferred pending the result of the proceedings in the courts, which were not likely to be heard for several months. The medical service subcommittee proposed to defer the hearing pending the result of the action but asked advice from the Ministry of Health. The Ministry stated that they were unable to give advice on the general question raised by the committee, but added that they saw no objection to the postponement of the investigation by the subcommittee pending the result of the other proceedings. The doctor then applied for leave of absence from his practice for a lengthy period, but as the committee were not satisfied that the absence would be due to a reasonable cause they refused. The doctor then gave three months' notice of his desire to withdraw from the medical list, which he had a perfect right to do. It became clear, in view of the time which must elapse before the case could be reached in the courts, that unless the hearing preceded the action in the courts the doctor would no longer be an insurance practitioner by the time the subcommittee could hear the case, and consequently if he were found to be culpable the committee would be placed in a position of considerable embarrassment. Fortunately perhaps, after much correspondence, the complaint to the committee was withdrawn, neither party being desirous apparently of running the risk of the legal action being prejudiced by the result of the medical service inquiry.

A Complaint that Failed

Article 33 (1) of the Medical Benefit Regulations gives power to a medical service subcommittee, if they think fit, to permit any person concerned in an investigation to be assisted in the presentation of his case by some other person, but no person is entitled to appear in the capacity of counsel, solicitor, or

other paid advocate. This permissive power to admit a "friend" must not be confused with the right of the secretary or other officer of the society or branch of which the insured person may be a member, and the secretary or other officer of the panel committee to be present, a right which so far as the panel committee officer is concerned is usually exercised. The Manchester medical service subcommittee recently heard a case in which the complainant, the mother of a deceased insured person, was assisted in the presentation of her case by a clergyman who was also a witness on her behalf.

The question arising was a comprehensive one covering alleged irregular and insufficient attention, the issue of certificates without seeing the patient, delay in recommending hospital treatment, and a complaint as to the circumstances under which the patient was sent to hospital during the night on which he died. The patient had a valvular heart lesion and following an attack of influenza a subacute malignant endocarditis developed; he was also anæmic. The first two points were not substantiated. With regard to the hospital treatment a specialist was called in—the patient's employers having assumed responsibility for the cost—and he advised hospital treatment to which both the patient and his mother were at first averse, but on the following day they changed their minds and informed the doctor, who immediately notified the specialist and asked him to arrange for admission as soon as possible. Admittedly delay did then occur, but as the arrangements for the admission of the patient to the hospital rested upon the consultant the respondent doctor could not be blamed, nor was it within the province of the committee to investigate the circumstances of the delay.

Meanwhile the doctor had continued to treat the patient and visited him on the afternoon of March 20th, 1935. During the night of March 21st–22nd the mother went to the doctor two or three times between 12.30 and 2.30 A.M., and it is agreed that she saw him twice. On the first occasion the doctor handed her a tablet of digitalin and strychnine which she was to administer to the patient and to let the doctor know if he did not improve. On the second occasion the doctor—who had been clearing up his work in preparation for a journey to Scotland to attend the funeral of his mother on the following day—was in his bath and to save disturbing the household answered the door himself clad only in a bath towel. He was told that the patient was no better and then decided that the only hope was to take the risk of securing the boy's immediate admission to hospital. It would have taken him some 25 minutes to dress and get to the patient and he therefore telephoned for an ambulance which arrived at the patient's house within five minutes and transported the boy to the hospital where he died before admission to a ward.

From the evidence of the doctor and of the specialist there was no hope of the patient's recovery, but it was thought that treatment in hospital might have prolonged his life. The subcommittee found that the charges of neglect had not been established, but they observed that in the light of after knowledge of the events they believed that a visit to the patient during the last night would have been the better course but they were satisfied, in the circumstances with which the doctor was faced at the time, that he took the action which he believed was in the best interests of the patient and relatives.

MEDICAL NEWS

Royal College of Surgeons of England

A quarterly meeting of the council was held on Oct. 10th with Sir Cuthbert Wallace, the president, in the chair. Dr. William Bradley Coley, of New York, was admitted an honorary fellow of the college and Mr. Joseph Jacobs, of Lewis's School, Pengam, was admitted as the sixth Macloghlin scholar. It was reported that at the promotion examination for 1935 the Sir Gilbert Blane gold medals had been awarded to Surgeon Lieutenant-Commander A. A. Pomfret and Surgeon Lieutenant-Commander W. G. C. Fitzpatrick.

Diplomas of membership were granted to the following candidates:—

T. D. Chablani, Bombay St. Geo.; B. P. Datta, Calcutta and Lond.; E. W. Knowles, Liverp.; and Phyllis J. M. Sykes, Univ. Coll.

Diplomas in anaesthetics were granted jointly with the Royal College of Physicians to the following:—

G. F. V. Anson, Herbert Charles, L. T. Clarke, Elsie C. Hanson, O. J. Murphy, and J. D. Stewart.

A series of demonstrations of specimens in the museum will be opened on Monday, Oct. 21st, when Dr. A. J. E. Cave will speak on the anatomy of the faucial tonsil. The second lecture will be given on Oct. 25th by Mr. C. P. G. Wakeley, on tumours of the brain and spinal cord. On Oct. 28th and Nov. 4th Dr. L. W. Proger will describe some diseases of bone, and on Nov. 1st and 8th Dr. Cave will deal with the anatomy and physiology of the human larynx. The lectures will be held at 5 p.m. at the College, Lincoln's Inn Fields, London, W.C., and are open to medical practitioners and advanced students.

University of London

The next award of the Rogers prize of £100, which is offered from time to time by the senate for the best essay on a medical or surgical subject, will be made in 1936. The subject chosen is the natural history of peptic ulcers. Further information will be found in our advertisement columns.

University of Dublin

At recent examinations at the School of Physic, Trinity College, the following candidates were successful:—

FINAL EXAMINATION FOR M.B., B.CH.

Part I. (*Pathology, Therapeutics, &c.*).—W. T. Kenny, Mandel Friedman, M. C. Brough, J. H. Mitchell, J. E. Gillespie, F. C. Heatley, Robert Pollock, J. C. Lambkin, P. G. Patton, Jasmine Taylor, O. M. Harrison, G. K. Donald, Grace M. Wild, R. J. Sandys, D. B. George, Patricia M. J. Conway, and J. N. G. Drury.

University of Wales

In a recent examination for Part II. of the diploma in public health the following candidates were successful:—

Robert Cameron, T. C. R. George, Joan E. Greener (with distinction), D. J. Jones, G. R. Jones, and J. M. Thomas.

University of Sheffield

On Oct. 11th H. A. Krebs, M.A. Camb., M.D. Hamburg, was appointed lecturer in pharmacology in the university. The title of emeritus professor was conferred on Dr. C. J. Patten, late professor of anatomy, and Mr. Miles Phillips, late professor of obstetrics and gynaecology.

The late Dr. John Stokes, of Sheffield, who died on June 5th, left property to the value of over £20,000. After a few small bequests, including £100 to the Children's Hospital, Sheffield, he left the residue of the property to the University. He expressed the wish that the legacy would be used to establish a fellowship in any subject tending to advance the science of medicine and alleviate the sum total of human suffering.

Royce Research Fellowships

The late Sir Henry Royce instructed that a tenth of his fortune should be used to promote medical research, and the money has been used for the establishment of two fellowships, each of £500 a year, for investigation of influenza and the common cold. One of the fellowships is held by Dr. C. H. S. Harris at the British Postgraduate Medical School, Hammersmith, and the second has now been awarded to Dr. Leslie Hoyle, demonstrator in pathology and bacteriology at Leeds Medical School. Dr. Hoyle will work at the University of Manchester. The fellowships are tenable for three years, and the holders will collaborate in their inquiries.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty held on Oct. 7th Gilbert Forbes, M.B. (Glasgow), and Hugh Gordon Neill, M.B. (Glasgow), were admitted to the fellowship.

St. John Clinic and Institute of Physical Medicine

A post-graduate course on practical methods of physical medicine will be held at the clinic, Ranelagh-road, London, S.W., on alternate Fridays, at 4.30 p.m., from Nov. 1st to March 20th. Sir Leonard Hill, F.R.S., will give the first lecture and will speak on the action of ultra-violet, visible, and infra-red rays.

Semon Lecture

This annual lecture will be delivered at the house of the Royal Society of Medicine, 1, Wimpole-street, W., at 5 p.m., on Thursday, Oct. 31st, by Sir StClair Thomson, who has chosen for his subject the Defences of the Air-passages. The lecture is given under the auspices of the University of London, and the chair will be taken by Mr. H. L. Eason, the Vice-Chancellor.

Chadwick Trust

Sir William Collins will preside at a lecture arranged by this Trust to be given by Captain R. St. Barbe Baker, founder of the Men of the Trees, in the hall of the Royal Geographical Society, Exhibition-road, Kensington Gore, on Wednesday, Oct. 23rd, at 8.15 p.m. He will speak on the contribution of trees to national health and efficiency.

Royal Dental Hospital of London

School of Dental Surgery.—The twenty-sixth annual At Home of this school will be held on Saturday, Nov. 23rd. The morning, from 9.30 a.m. to 12.30 p.m., will be devoted to demonstrations at the in-patient department of Charing Cross Hospital and in the various departments of the Royal Dental Hospital, where there will also be an exhibition of clinical cases, photographs, and drawings in the afternoon.

Royal Institution

The afternoon lecture courses at the Royal Institution this winter include a survey of modern views on nutrition by Prof. Edward Mellanby, F.R.S., secretary of the Medical Research Council, to be given at 5.15 p.m. on Tuesdays, Nov. 26th, Dec. 3rd, 10th, and 17th. The Christmas course of six lectures for children will be given by Mr. C. E. K. Mees, D.Sc., director of research at the Eastman Kodak Company, on photography. The address of the institution is 21, Albemarle-street, London, W. 1.

Prize for Research in Rheumatism

The Russian Government, after consultation with the Ligue Internationale contre le Rhumatisme, has offered two prizes, each of 1000 gold roubles (about £180), for investigations carried out during the last ten years on clinical, scientific, or social aspects of rheumatism. Papers may be written in either English, German, or French, and four copies should be sent to the secretary of the league, Dr. J. van Breemen, Keizersgracht 489, Amsterdam, before Nov. 15th.

Lectures for Parents

A special autumn course for parents has been arranged by the Institute of Medical Psychology, and will be held at the clinic in Malet-place, London, W.C., on Tuesdays, at 6 p.m., from Oct. 22nd to Dec. 10th. The course will be in charge of Dr. Emanuel Miller and will cover such questions as the conflict of parents' temperaments, the sex education of children, and the general management of adolescence.

Midwives' Institute

Lady Forber (Dr. Janet Lane-Claypon) will deliver the Fynes-Clinton memorial lecture at this institute, 57, Lower Belgrave-street, London, S.W., at 5.30 p.m. on Oct. 24th. She will make a preliminary report on the present conditions of midwifery practice, based on a questionnaire issued by the institute to 8000 independent midwives in England and Wales. Lady Williams will preside. Free tickets will be available at the institute.

Dr. J. A. Ryle, regius professor of physic in the University of Cambridge, and Dr. Matthew Stewart, professor of pathology in the University of Leeds, have been appointed members of the Medical Research Council in succession to Lord Dawson of Penn and Prof. A. E. Boycott, F.R.S.

Whitworth Hospital, Darley Dale

There is a deficit of £3633 on this hospital, the loss on last year's working being £349, as against £385 in the previous year. Road accidents involve the hospital in a great deal of expense, and it has been necessary to spend money on bringing the operating theatre up to date.

Smallwood Hospital, Redditch

An appeal to raise £30,000 for extensions to this institution is to be launched. Twenty additional beds are required and improvements are needed in the X ray, massage, and out-patients' departments.

Essex County Hospital, Colchester

An extension scheme costing £40,000 is contemplated at this hospital to meet the future requirements of the large area which it serves. The contributory scheme showed an increase last year of over £400 in the country districts and amounted in all to £6197. The collection of £5833 from the workers of the borough of Colchester brought the total sum raised to over £12,000.

Bureau of Hygiene and Tropical Diseases

Dr. Harold Scott has now taken up his duties as director of this bureau in succession to Sir Arthur Bagshawe.

Educated at the Mercers' and City of London Schools, Dr. Scott received his medical training at St. Bartholomew's and St. Thomas's Hospitals and at University College, subsequently going on to Copenhagen. Qualifying with the Conjoint Board in 1897, he was house physician at St. Thomas's before serving in the South African war as a captain in the R.A.M.C. In 1900 he took the M.B. Lond. and was appointed Government bacteriologist in Jamaica, taking a similar position later at Hong-Kong. During the late war he was pathologist at the Cambridge Hospital, Aldershot, in charge of mobile laboratory No. 13. In 1930 he was appointed assistant director of the Bureau of Hygiene and Tropical Diseases, having previously been on the staff of the London School of Hygiene and Tropical Medicine as Milner research fellow in comparative pathology, holding at the same time the post of pathologist to the Zoological Society of London. He also lectured on tropical disease at the Westminster Hospital medical school, examined in tropical medicine and surgery for the Conjoint Board, and acted as medical secretary of the Colonial Medical Research Committee. He collaborated with the late Sir Andrew Balfour in a survey entitled *Health Problems of the Empire—Past, Present, and Future*, and in 1930 his important review of tuberculosis in man and lower animals was published as a special report (No. 149) by the Medical Research Council. He has contributed frequently to the *Annals of Tropical Medicine and Parasitology*, and is the author of a recent work entitled "Notable Epidemics." He was elected F.R.C.P. Lond. in 1925, and is a fellow of the Royal Society of Edinburgh.

Medical Missionaries in Abyssinia

There is some doubt whether the evacuation of Addis Ababa by British subjects will apply to the missionaries working there. It is stated that all the representatives of the Missionary Society, numbering about fifteen, have had at least a short medical training, and have all offered for Red Cross work. We are informed that Mr. and Mrs. Colin Mackenzie have been in charge for some time of the Swedish Hospital at Harar, while Dr. and Mrs. Kenneth Buxton were due at Jibuti on Monday last and are taking medical equipment to Harar. Dr. Lionel Gurney is at the hospital at Asba Tafari; while Dr. Ted Gurney, his brother, and Mrs. Gurney are preparing to leave England for Abyssinia as soon as possible. The Sudan Interior Mission, which sent three new missionaries to Abyssinia last week, also hopes that its British missionaries will be allowed to remain. Dr. T. A. Lambie, formerly an American, who is in charge of the Mission's work in Abyssinia, is a naturalised Abyssinian and will not be affected by the order. But there are also about 25 British missionaries, mostly Canadian, Australian, and New Zealand, with the Mission, besides nearly 40 Americans. Some of them, including Dr. E. R. Hooper, the Canadian in charge of the leprosarium at Addis Ababa, are medically qualified, and there are at least six qualified nurses. Most of the rest, if not all, have taken a medical course in their missionary training, and will be able to offer for Red Cross work.

Films for Nurses

For the first time in Liverpool a film has been shown in a training class for nurses. The film was sponsored by the Merseyside Film Society and was shown at Walton Hospital.

Coventry and Warwickshire Hospital

The board of management hope to begin the extensions to this hospital some time after Easter. The fund now stands at £95,000, but £120,000 will probably be required.

Lady Chichester Hospital, Hove

On Oct. 1st the Bishop of Chichester dedicated to the memory of Bishop Russell Wakefield a new consulting-room for the medical staff of this hospital. He also dedicated a new wing which has been built by the trustees of the John Howard bequest.

New Hospital for Wakefield

The Mayor of Wakefield has opened a new municipal maternity hospital, child welfare centre, and antenatal clinic at Manygates Park, Wakefield. The hospital has accommodation for 35 patients, and was built at a cost of £27,000.

Society for Relief of Widows and Orphans of Medical Men

At a meeting of the court of directors, held on Oct. 9th, Mr. V. Warren Low being in the chair, seven new members were elected. A grant of £52 10s. a year for five years was made to a widow to enable her daughter to study medicine; the daughter had already passed her preliminary medical examination. A sum of £645 was voted as a Christmas present, to be distributed as follows: widows over 75 to receive £15 each, under 75 each £10, orphans £10 each. A widow who had died since the last meeting of the court came on the funds in 1919 and had received in grants £1155. Membership in the society is open to any registered medical man, who at the time of his election is residing within a twenty-mile radius of Charing Cross. Full particulars from the secretary, 11, Chandos-street, London, W. 1.

Chelsea Clinical Society

Mr. H. Paxton Baylis, the president, took the chair at the annual dinner of this society held at the Rembrandt Hotel on Tuesday last. Field-Marshal Lord Milne, who proposed the health of the Society, remarked that in the absence of any direct information he had consulted the dictionary for the meaning of a clinical society. Combining the information given under the two words, he had decided that it was a number of persons associated by a common interest confined to bed through sickness. The evening which he had spent had not, however, borne out this expectation. During the war he had come into close contact with the medical profession, and without its aid he would not have been there that evening. As chairman of a physical training institute in the East End, he urged the profession to induce the parents of the country to take more interest in the physical education of their children. As an active soldier, he had found a lamentable physique among the upper classes. Physical training was much more important than games. The President, in his reply, reported that the membership of the society and the attendance at its meetings had increased. In 1897 it had numbered 17 members, who had met in a dispensary in Chelsea under the presidency of Dr. Foster Palmer. Its members were now 230, and it met in an atmosphere of camaraderie and good fellowship. Just as in the past a physician had given medicine in some palatable disguise, so the society administered a basis of good food and wine before the discussion of its medical problems. Dr. Desmond MacManus, proposing the health of the guests, spoke of Lord Milne's drive and energy as chairman of the Cancer Hospital. Mr. H. L. Eason, in reply, declared that of all the faculties of the University of London the most distinguished was that of medicine; it was unparalleled throughout the Empire for wealth of clinical material, hospitals, and societies, and it provided between 40 and 50 per cent. of the whole medical profession of England, Scotland, and Wales. Dr. Bernard Myers, who also replied, spoke of the incalculable value of medical societies.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Oct. 22nd.

Medicine. 5 P.M. Dr. Arnold Stott and Dr. D. Evan Bedford: The Recognition of Myocardial Disease. Dr. A. G. Gibson will also speak.

WEDNESDAY.

Comparative Medicine. 5 P.M. Prof. J. C. G. Ledingham, F.R.S.: The Comparative Study of Clinically Allied Viruses: Some Unsolved Problems of Edward Jenner (presidential address).

THURSDAY.

Urology. 8.30 P.M. Mr. R. Ogier Ward: Some Remarks on Vesical Diverticula (presidential address).

FRIDAY.

Disease in Children. 5 P.M. (Cases at 4.30 P.M.) Dr. E. A. Cockayne: 1. Arachnodactylia with Congenital Heart Disease († Intraventricular Septum). Dr. R. Cove-Smith and Dr. Alan Moncrieff: 2. Defective Saliva and Digestive Disturbance. Dr. E. Fletcher and Mr. Holmes Sellers: 3. Lobectomy for Bronchiectasia. Dr. A. M. Stewart-Wallace (for Dr. R. A. Rowlands): 4. A Probable Case of Pick's Disease. 5. Case for Diagnosis. 1 Cerebral Degeneration.

Epidemiology and State Medicine. 8.15 P.M. Surgeon Captain S. F. Dudley: On the Biological Approach to the Study of Epidemiology (presidential address).

Physical Medicine. 8.30 P.M. Dr. C. B. Heald: Electrotherapy 1910-35, including Experiments in the Induction of Artificial Fever (presidential address).

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.

MONDAY, Oct. 21st.—8 P.M. Annual General Meeting. 8.30 P.M., Prof. G. E. Gask: Changing Surgery (presidential address).

MEDICO-LEGAL SOCIETY.

THURSDAY, Oct. 24th.—8.30 P.M. (Manson House, 26, Portland-place, W.). Mr. O. A. Mitchell, D.Sc.: Forensic Chemistry in relation to Medicine (presidential address).

EUGENICS SOCIETY.

TUESDAY, Oct. 22nd.—5.15 P.M. (rooms of the Linnean Society, Burlington House, Piccadilly, W.). Mr. Herbert Brewer: Euteleogenesis—Objections and Criticisms Considered.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY, 49, Leicester-square W.C.

WEDNESDAY, Oct. 23rd.—4.30 P.M., Clinical Cases.

BRITISH ORTHOPÆDIC ASSOCIATION.

FRIDAY, Oct. 25th, and SATURDAY.—Annual meeting at Manchester.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Oct. 21st.—5 P.M., Dr. A. J. E. Cave: The Anatomy of the Fauical Tonsil.

FRIDAY.—5 P.M., Mr. C. P. G. Wakeley: Tumours of the Brain and Spine.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 21st, to SATURDAY, Oct. 26th.—INFANTS HOSPITAL, Vincent-square, S.W. Mon., Wed., and Fri., 8 P.M., course for the F.R.C.S. Primary (Anatomy and Physiology).—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. All-day course in gynecology.—WEST END HOSPITAL FOR NERVOUS DISEASES, Welbeck-street, W. All-day course in neurology.—ST. JOHN CLINIC AND INSTITUTE OF PHYSICAL MEDICINE, Ranelagh-road, S.W. Sat. and Sun., course in physical medicine.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W. Thurs., 4 P.M., Mr. Albert Davis: Neurosurgery in the Relief of Gynecological Pain.—NATIONAL TEMPERANCE HOSPITAL, Hampstead-road, N.W. Tues., 8.30 P.M., Dr. R. D. Lawrence: Pancreas. Thurs., 8.30 P.M., Dr. S. Lett Simpson: Adrenal. Courses and lectures arranged by the Fellowship are open only to members and associates.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

THURSDAY, Oct. 24th.—3 P.M., Dr. Russell Brain: Demonstrations.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL, N.W.

WEDNESDAY, Oct. 23rd.—4 P.M., Dr. Saxby Willis: Thoracic Pain.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Oct. 23rd.—4.30 P.M., Mr. W. K. Irwin: Some Important Prostatic Diseases.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 24th.—2 P.M., Mr. T. Twistington Higgins: Some Points in Genito-urinary Surgery. 3 P.M., Dr. A. Signy: Specific Immunisation (III). Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Oct. 21st.—3.30 P.M., Dr. Kinnier Wilson: Organic Dementia (I).

TUESDAY.—3.30 P.M., Dr. Purdon Martin: The Cranial Nerves (III).

WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.

THURSDAY.—3.30 P.M., Dr. Riddoch: The Sensory System (III).

FRIDAY.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (III).

Out-patient clinic daily at 2 P.M.

WEST LONDON POST-GRADUATE COLLEGE, W.6.

MONDAY, Oct. 21st.—10 A.M., medical and surgical wards, skin clinic. 2 P.M., gynecological and surgical wards, eye and gynecological clinics. 4.15 P.M., Mr. Green-Armstrong: Errors in Treatment.

TUESDAY.—10 A.M., medical wards and dental clinic, 11 A.M., surgical wards. 2 P.M., throat clinic. 4.15 P.M., Dr. Konstam: The Thyroid and the Heart.

WEDNESDAY.—10 A.M., children's wards and clinic, medical wards. 2 P.M., eye clinic. 4.15 P.M., Dr. Archer: Biochemical Demonstration.

THURSDAY.—10 A.M., neurological and gynecological clinics. Noon, fracture clinic. 2 P.M., eye and genito-urinary clinics. 4 P.M., venereal diseases.

FRIDAY.—10 A.M., skin and dental clinics. Noon, Lecture on Treatment. 2 P.M., throat clinic. 4.15 P.M., Dr. Hugh Gordon: Differential Diagnosis of Common Skin Diseases.

SATURDAY.—10 A.M., surgical and children's clinics, medical wards. The lectures at 4.15 P.M. are open to all medical practitioners without fee. Operations and medical and surgical clinics daily at 2 P.M.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

TUESDAY, Oct. 22nd.—5 P.M., Dr. J. E. M. Wigley: Tuberculosis Cutis.

THURSDAY.—5 P.M., Dr. H. W. Barber: Psoriasis.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

THURSDAY, Oct. 24th.—9 P.M., Mr. J. B. Hunter: Surgical Treatment of Pulmonary Tuberculosis.

UNIVERSITY OF LONDON.

TUESDAY, Oct. 22nd.—5 P.M. (University College Hospital Medical School), Prof. Charles Singer: History of Museums and Collections.

TUESDAY, THURSDAY, and FRIDAY.—5.30 P.M. (University College), Prof. Pol Gerard: Comparative Histopathology of the Vertebrate Nephron.

LONDON SCHOOL OF HYGIENE, Keppel-street, W.C.

WEDNESDAY, Oct. 23rd.—4.30 P.M., Prof. R. A. Fisher, F.R.S.: Eugenics and National Health (second lecture).

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.

TUESDAY, Oct. 22nd.—6 P.M., Dr. Emanuel Miller: Problems of Parenthood (first of a course of eight weekly lectures).

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, Oct. 23rd.—3.30 P.M., Dr. A. A. Moncrieff: The Early Weeks of Life in relation to the Health of the Adolescent.

UNIVERSITY OF SHEFFIELD.

FRIDAY, Oct. 25th.—3 P.M. (Royal Infirmary), Mr. J. H. Cobb: Ear, Nose, and Throat Clinic. 3 P.M. (Royal Hospital), Dr. Rupert Hallam: Dermatological Clinic. Mr. E. Gordon Mackie: Ophthalmological Clinic.

SUNDAY.—10.30 A.M. (Royal Hospital), Dr. C. Gray Imrie and Dr. A. Gurney Yates: Medical cases. Mr. Wilfred Hynes: Surgical cases. 10.30 A.M. (Jessop Hospital), Mr. Glyn Davies: Gynecological cases.

UNIVERSITY OF BRISTOL.

TUESDAY, Oct. 22nd.—5.15 P.M., Dr. Macdonald Critchley: Occurrence of Pain (Long Fox lecture).

GENERAL INFIRMARY, Leeds.

TUESDAY, Oct. 22nd.—3.30 P.M., Dr. Vining: Convulsive Disorders of Childhood.

PUBLIC DISPENSARY AND HOSPITAL, Leeds.

WEDNESDAY, Oct. 23rd.—4 P.M., Mr. A. D. Sharp: Ear, Nose, and Throat—selected cases.

ANCOATS HOSPITAL, Manchester.

THURSDAY, Oct. 24th.—4.15 P.M., Dr. R. Ellis: Medical Treatment of Urinary Infections.

ROYAL INFIRMARY, Manchester.

TUESDAY, Oct. 22nd.—4.15 P.M., Dr. Norman Kletz: Functional Disorders of the Digestive System.

FRIDAY.—4.15 P.M., Mr. A. Graham Bryce: Demonstration of surgical cases.

WAR MEMORIAL HOSPITAL, SHOOTER'S HILL.—Extensions to this hospital are urgently needed and an appeal for £40,000 is being made. A nurses' home is required and the maternity ward, which has only eight beds, is inadequate for the needs of the district. Waiting-lists are lengthening, emergency beds have been brought into use, and expenditure is increased by nurses having to sleep in quarters outside the hospital.

Appointments

BARLING, B., M.D., M.R.C.P. Lond., has been appointed Deputy Medical Superintendent, Grade II., at St. Mary Abbots Hospital, L.C.C.
 COHEN, H. M., M.B. Liverp., D.P.H., Senior School Medical Officer for the Assistant Radio-logist at the
 JOHNSTONE, M. B.
 MARSHALL, S. F., M.B. Lond., Assistant Medical Officer and Pathologist at the Old Church Hospital, Romford.
 MORLEY, JOHN, Ch.M. Manch., F.R.C.S. Eng., Hon. Consulting Surgeon to the Manchester Babies' Hospital.
 PLATT, HARRY, M.S. Lond., F.R.C.S. Eng., Hon. Consulting Orthopaedic Surgeon to the Manchester Babies' Hospital, Kingston and District Hospital.—The following appointments are announced:—
 WARNER, E. O., M.D., M.R.C.P. Lond., Visiting Physician; GRIFFITHS, J. IVOR, M.B. Lond., F.R.C.S. Eng., Visiting Aural Surgeon; and
 TODD, A. H., M.S. Lond., F.R.C.S. Eng., Visiting Orthopaedic Surgeon.

Vacancies

For further information refer to the advertisement columns
Abyssinia Ambulance Unit.—Medical Officers.
Ashton-under-Lyne District Infirmary.—Res. Surg. O. At rate of £200.
Bath and Wessex Children's Orthopaedic Hospital, Combe Park.—H.S. At rate of £120.
Birmingham, Erdington House.—Jun. Asst. M.O. At rate of £200.
Bristol Eyc Hospital.—Jun. Res. H.S. £100.
Bristol, Ham Green Hospital and Sanatorium.—Jun. Asst. Res. M.O. £250.
Burton-on-Trent General Infirmary.—H.P. and Cas. O. £150.
Buxton Clinic for Rheumatism and Allied Diseases.—H.P. At rate of £150.
Cairo, Egypt, Giza Memorial Ophthalmic Laboratory.—Asst. Surgeon. L.E.800.
Cambridgeshire C.C.—Asst. County M.O. £600.
Cardiff, King Edward VII. Welsh National Memorial Association.—Asst. Res. M.O. for Glan Ely Tuberculosis Hospital. £200. Also Asst. Res. M.O. for South Wales Sanatorium. £200.
Cardiff Royal Infirmary.—Cas. Surg. O. At rate of £75.
Chesterfield Poor Law Institution and Infirmary.—Res. M.O. £150.
Colonial Medical Service.—Medical Officers.
Doncaster Royal Infirmary.—H.S. At rate of £175.
Dreadnought Hospital, Greenwich.—Anaesthetist. 50 Guineas.
Durham County Council.—District Tuber. M.O. £500. Also M.O. for Earl's House Sanatorium. £450.
Ealing Borough.—Ophth. Surgeon. £275.
Godalming, King George V. Sanatorium.—Asst. M.O. £350.
Golden-square Throat, Nose, and Ear Hospital, IV.—H.S. £100.
Halifax General Hospital.—Jun. Res. M.O. £250.
Hampstead General and N.W. London Hospital, Haverstock Hill, N.W.—H.S. At rate of £100.
Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.S. At rate of £75.
Hostel of St. Luke, 14, Fitzroy-square, IV.—Res. M.O. At rate of £200.
Hove General Hospital.—Res. M.O. At rate of £150.
Huddersfield Royal Infirmary.—H.S. for Eye, Ear, and Obstet. Depts. At rate of £150.
Jersey General Hospital and Poor Law Infirmary.—Asst. Res. M.O. At rate of £150.
Kingston-upon-Hull City and County.—Asst. M.O.H. £600.
Lancaster Royal Infirmary.—Jun. H.S. At rate of £130.
Lewisham Hospital, High-street, S.E.—Asst. M.O. £350.
Leytonstone Children's Home, High-road, E.—Part-time M.O. At rate of £210.
Liverpool University.—Lectureship in Bacteriology. £400.
L.C.C.—Temporary District M.O.'s for Special Areas.—£100—£235.
London Jewish Hospital, Stepney Green, E.—Res. M.O. and H.P. At rate of £150. Also H.S. and Cas. O. Each at rate of £100.
London
London
London Coll.
Manches
Middlesex
Mount Vernon Hospital, Northwood, Middlesex.—H.S. At rate of £150.
New Zealand, Wanganui Hospital.—Radiologist. £800.
Nottingham, City Mental Hospital.—Jun. Asst. M.O. £350.
Portsmouth Royal Hospital.—H.S. At rate of £130.
Prince of Wales's General Hospital, N.—Hon. Physician to Dept. of Physical Medicine.
Princess Louise Kensington Hospital for Children, St. Quinton-avenue, W.—Hon. Asst. Physician. Also two Clin. Assts. for Out-patient Sessions.
Queen's Hospital for Children, Hackney, E.—Dermatologist.
Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.
Royal Dental Hospital of London, 32, Leicester-square, W.C.—Two Part-time House Anaesthetists. 10s. 6d. per session.
Royal Free Hospital, Gray's Inn-road, W.C.—Dermatologist.

St. Charles' Hospital, St. Charles-square, Ladbroke-grove, W.—Asst. M.O. £350.
St. James' Hospital, Ousley-road, Balham, S.W.—Asst. M.O. £350.
St. Mary's Hospital, W.—Second Obstet. Surgeon for Out-patients.
St. Thomas's Hospital, S.E.—Ophthalmic Surgeon.
Sheffield Royal Hospital.—Clin. Asst. to Ophth. Dept. £300.
Sheffield Royal Infirmary.—H.S. Also Aural H.S. Each at rate of £80.
Sheffield, Winter-street Hospital.—Asst. Tuber. O. £350.
Southampton Borough General Hospital.—Asst. Res. M.O. £350.
Southend-on-Sea County Borough.—Asst. M.O.H. £600.
South London Hospital for Women, Clapham Common, S.W.—Clin. Asst.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. Res. H.S.'s. At rate of £150 and £100 respectively.
West Suffolk County Council.—Asst. County M.O. and Asst. School M.O. £500.
Wolverhampton Royal Hospital.—Asst. Pathologist and Med. Reg. £150.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Helensburgh (Dumbartonshire) and Rochdale (Lancashire).

Births, Marriages, and Deaths

BIRTHS

LLOYD.—On Oct. 6th, at Cheltenham, the wife of J. P. F. Lloyd, F.R.C.S. Eng., of a son.
 MCCOMAS.—On Oct. 11th, at Park Vale Nursing Home, Streatham, the wife of Geoffrey McComas, M.D., M.R.C.P. Lond., of a son.
 ROSE.—On Oct. 6th, at Welbeck-street, W., the wife of Dr. S. Rose, of Wimbledon, of a daughter.
 STANLEY.—On Oct. 5th, at Ware, Herts, the wife of Brian Stanley, B.Sc., M.R.C.P. Lond., of a son.
 STANLEY.—On Oct. 10th, at East Grinstead, the wife of Roger Stanley, M.R.C.S. Eng., of a son.
 WILSON.—On Oct. 6th, at St. Dennis, Cornwall, the wife of C. M. Wilson, M.B., Ch.B. Edin., of a daughter.

MARRIAGES

CUTTING—PHIBBS.—On Oct. 5th, at All Souls', Langham-place, Philip Edwin James Cutting, M.D., B.S. Lond., D.T.M. Liverp., C.M.S. Hospital, C. only child of the Rev. Alfred Phibbs . . .
 HALL—GOULD.—On Oct. 5th, at the . . .
 Watford, Herts, Gilbert Steward . . .
 to Mary Elaine Gould, M.B., B.S. Lond., elder daughter of the Rev. F. J. Gould, of Watford.
 HOEY—SMALL.—On Oct. 8th, in London, Trevor Hoey, M.B. Oxon., M.R.C.S. Eng., to Elizabeth Napier Small.
 PRICE—BROCKBANK.—On Oct. 5th, at Great Barton Parish Church, Cyril Frederick Price, M.B., B.S., to Dora Elizabeth Brockbank, M.B., B.S. Lond.

SILVER WEDDING

RAVEN—ROBERTSON.—On Oct. 11th, 1910, at Bishopsbourne, near Canterbury, Hugh M. Raven, M.R.C.S., L.R.C.P., eldest son of the late Thomas Raven, M.R.C.S., of Broadstairs, to Jean, daughter of the late John Robertson, of Alassio, Italy.

DEATHS

CORTHORN.—On Oct. 8th, Alice Mary Corthorn, M.B., B.S. Lond., B.Sc., aged 76.
 DWYER.—On Oct. 10th, in Dublin, Sir Frederick Conway Dwyer, M.D., F.R.C.S.I., ex-President of the Royal College of Surgeons in Ireland, aged 75.
 MINETT.—On Oct. 5th, at Uplyme, Devon, E. P. Minett, M.D. Brux., D.P.H. Camb., D.T.M. and H.
 NIBLOCK.—On Oct. 10th, at Bournemouth, Lieut.-Col. William James Niblock, M.B., F.R.C.S.I., I.M.S. (ret.).
 SMITH.—On Oct. 6th, at Ambleside, Charles Edwin Smith, M.R.C.S. Eng., late of Stretford.
 WILKINSON.—On Oct. 8th, at Swindon, Wilts, St. John Wilkinson, F.R.C.S. Edin., D.P.H., retired Major, R.A.M.C.
 WILSON.—On Oct. 5th, at Bourton, Dorset, after a long illness, Archer Herbert Wilson, M.A., M.B. Camb., late of the West African Medical Staff, South Nigeria.
 YOUNAN.—On Oct. 11th, at Minehead, Arthur Charles Younan, M.B. Edin., retired Lieut.-Col., I.M.S., late Med. Off., 25th Punjabs, Rawal Pindt.

N.B.—A fee of 1s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

MORE HOSPITALS FOR SOUTH SHIELDS.—In a special report to the town council, Dr. Campbell Lyons, the medical officer, recommends the erection of a new isolation hospital, a maternity hospital, and a new municipal clinic. It is suggested that assistance for the schemes should be sought from the Commissioner for Special Areas.

NOTES, COMMENTS, AND ABSTRACTS

THE QUETTA EARTHQUAKE

THE medical problems of the earthquake at Quetta were among the most formidable of all the problems which that disaster involved. Most fortunately, the earthquake which destroyed the city and the Royal Air Force lines with great loss of life largely spared the cantonments and left 12,000 able-bodied, disciplined troops available for rescue work. Every available army lorry and vehicle was sent straight to the devastated areas full of troops, and was then used to augment the ambulance services sent down by the British and military hospitals. A relief headquarters was opened in the ruined Quetta Club in the early morning, and the rescue work was at once organised into areas by General Karslake; the police were all dead and there was no civil machinery left. The city and the Civil Lines were subdivided into unit allotments, medical aid posts were arranged, and ambulance services organised. Extra medical assistance was requisitioned from India, and the local medical staffs of the two military hospitals, assisted by civilian doctors, carried on. The civil and missionary hospitals had been destroyed and the military hospital buildings had been rendered unsafe, so the verandahs and tents were used instead, with stretchers and mattresses instead of beds. Before dawn a hundred officers' wives had reported for duty as emergency nurses. The brunt of the rescue work fell inevitably on the medical profession, and they rose to the occasion superbly; how well is graphically related in the official account just published by the Government of India.

Many of those who worked without ceasing for the next week had already been injured; one doctor reported for duty immediately on his rescue after lying buried in the ruins of his bungalow for several hours. The Indian Military Hospital, with seven doctors, admitted 4500 injured in the first two days; the staff performed 450 major operations, gave 1200 anaesthetics, and set 300 fractures. In the first fortnight nearly 25,000 patients were treated. Fortunately there was a full supply of all medical and surgical necessities.

The problems of sanitation were pressing, and the presence of human and animal corpses became a deadly menace; but so efficient were the methods adopted that no epidemic broke out. The task of the rescuers was immensely lightened by headquarters, for the Commander-in-Chief at once put all the resources of the Army in India at their disposal. Officers, nurses, and medical stores were immediately sent to Quetta by air; three sections of a field ambulance from Waziristan and two sanitary sections from the Eastern Command were mobilised and sent to Quetta, and six tons of medical stores were dispatched from various centres in India. The Royal Air Force, with the Viceroy's own aeroplane, the *Star of India*, flew backwards and forwards from June 1st to the 19th, flying 775 hours in trying weather conditions. They conveyed, besides medical personnel, over 12,000 lb. of medical stores and tinned goods, 4300 lb. of clothing, an X ray apparatus and a wireless set, and evacuated 99 adults and 41 children. The Punjab Government sent doctors, nurses, and medical assistants, and looked after refugees who arrived in the province, as quickly as possible, with large supplies of stores, and the Punjab Red Cross organisation sent bandages and clothing of all kinds. A strong contingent of Boy Scouts left for Quetta at once, and a private medical aid detachment was taken from Multan by a public-spirited Indian. Between ten and fifteen thousand Punjabi refugees returned to their province during the fortnight after the earthquake. The Mayo Hospital at Lahore was expanded to accommodate hundreds of cases of injury; the ordinary hospital staff was reinforced by voluntary helpers, and rest camps were established at most of the large towns.

The response from the public in the way of personal service, gifts of money, clothes, and food was remarkable, and Indian ladies of good position came forward to help in hospitals and first-aid stations. The Red Cross Association, St. John Ambulance, and the Boy Scouts Association did excellent work.

The public health commissioner, after examining the position, reported that immediate large-scale operations were to be deprecated owing to the danger to health which the simultaneous exhumation of large numbers of bodies would cause. It was, however, proposed that the main shopping areas should be salvaged and the broader thoroughfares cleared. This was done, and salvage was also carried out in a certain number of shops and houses in the city where the damage was small. A completely organised labour corps of 2000 men set to work to clear the streets. During these excavations hundreds of bodies were dug up, bearing the appearance of having been killed outright by the first shock. An extraordinary story arose that a sweetmeat seller had dug his way out of his ruined house after 47 days' imprisonment, but this was not confirmed. If Quetta is to be rebuilt, the task will be an enormous one, but the Government will certainly not again employ their servants in the area unless they are satisfied that similar effects from future earthquakes can be prevented.

BIOLOGY IN SCHOOLS

THE movement for the adequate teaching of biology in schools is now being reflected in the production of books designed to facilitate class-instruction. Three that have reached us recently approach the subject from different, but in each case original, points of view.

Mr. Palmer makes a definite break away from the traditional text-book of elementary biology.¹ Abandoning completely the "type" system the author has endeavoured to give a general idea of the manner in which animals and plants function, the various functions being discussed separately. Hitherto elementary physiology has been illustrated mainly from plants. The suggestions given here for practical work on animals are welcome. The second half of the book deals briefly with the main characteristics of the principal groups of organisms with the minimum of anatomical detail. Two concluding chapters deal with Evolution and Heredity and with scientific method. Mr. Palmer is obviously an enthusiast and his book is inspiring. Sometimes, however, he betrays a certain lack of understanding of the mind of the child for whom he is writing. His manner savours a little of the well-informed lecturer trying his hand at school teaching and much interested in the experiment. In some places—e.g., in his analysis of the chemistry of muscle contraction—he confuses the issue with unnecessary detail. At other times, as when stating the functions of the ductless glands and of the chromosomes, he forgets that such facts are of little interest without some mention of the evidence on which they are based. It is doubtful also whether the final chapter on the methods of science will evoke much response. The nature of induction, hypotheses, &c., should be self-evident from the rest of the book. Few children would interest themselves in these principles as abstractions, and clear thinking may even be hindered by a too early attempt to tabulate the methods involved. The author's attitude is clearly mechanistic. Without disputing this point of view, it might be pointed out that a child does not naturally look upon living things in this light, and that some bridge must be built between the common-sense view and the scientific explanations of living things.

¹ *Living Things*. By Richard Palmer, Lecturer in Education in the University of Liverpool, formerly Assistant Lecturer in Zoology, University College, London. London: George Allen and Unwin Ltd. 1935. Pp. 400. 7s. 6d.

It is therefore to be regretted that, though the word "organism" is often quoted, there is no note on the meaning of the word nor any discussion of the fundamental problem of organisation.

Until recently the teaching of biology in schools has usually taken the form of dilettante nature study at early stages followed by a course on the anatomy of a series of dead animals in preparation for examinations. It is now generally realised that the main objective of biology in schools should be the study of living animals in their proper environment and that this study can be approached in a scientific manner. There are, however, many technical difficulties to be overcome. To obtain the necessary animals and to keep them in a healthy condition and to devise suitable experiments to illustrate their activities requires time and experience. Mr. Green² not only gives some useful information on histological, microscopical, and dissection technique (which can be found elsewhere), but also describes methods of making and maintaining aquaria and vivaria and of feeding various animals. Teachers should welcome a book which brings this much needed information together. It would have been of even greater value had the author included more suggestions for the performing of elementary physiological experiments.

Miss Phillips and Miss Cox start their book³ by discussing the value of biology in the very earliest stages of education. They point out that biology, as well as the more "exact" sciences, can afford a training in accurate observation and logical reasoning. A passionate interest in living things is natural to a young child, but to widen this interest without destroying it demands the greatest skill on the part of the teacher. Enthusiasm for the subject, though essential, is not enough; it is necessary to understand the minds of children at different ages and to plan a course in such a way that sound knowledge is imparted while interest is maintained. Many hints are given in this book which should prove of value to teachers, and practical suggestions are made for courses in class and field work throughout the year for children of different ages.

DR. (BATH) OLIVER

NEXT Thursday the Wine and Food Society meets in Bath, and one of its pleasant duties is to unveil a memorial to Dr. William Oliver, F.R.S., inventor of the famous biscuit. Dr. Oliver was one of the founders of the Bath Royal Mineral Water Hospital, and testimony not only to his medical skill but to his many interests and his literary aptitude is to be found in the letters of his contemporaries. Though no doubt these polite accomplishments appeal to the members of the Wine and Food Society it is his work as an innovator that they delight to honour. Shortly before his death in 1764 he confided the recipe of the biscuits to his coachman, Atkins by name. He also gave the man £100 and ten sacks of the finest wheat flour; and on this foundation Atkins opened a shop in Green-street and soon acquired a large fortune from the sale of "Bath Oliver's."

EXAMINATION PAPERS EXAMINED

THE man on the job may be supposed to know when a tool is missing, and Dr. Mitchell Heggs tells us in the preface to his collection of papers for the London M.B. finals⁴ that he realised the need for such a book when he was working for this examination. The questions, which are taken from papers set during

the years 1920-35, are classified under the general headings of surgery, obstetrics and gynaecology, medicine, forensic medicine, public health, and pathology, and are further arranged in suitable subdivisions. Each is dated, so that the statistically minded may estimate its chances of revival; but Dr. Heggs, alas, attempts neither prophecy nor comment. Needless to say his book as a whole tends to emphasise the combatant rather than the constructive side of medical studies. But no doubt it will sometimes give substantial aid towards the defeat of the London examiners.

A USEFUL ADAPTER

Dr. OLIVER WALKER writes: It may interest some of our readers to know that they can obtain an adapter

making an airtight joint between a "Record" syringe and a gum elastic or rubber catheter of any size. It will be found of use in blowing through a blocked catheter in situ or for irrigation, aspiration, and the like. The adapter, which is made of chromium-plated metal, can be obtained from Messrs. Allen and Hanburys Ltd.

INSURANCE AGAINST PROLONGED ILLNESS

A BENEFICIARY writes: "Will you allow me to advise every medical practitioner and dentist to insure with the Medical Sickness Annuity and Life Assurance Society, which has been founded by medicals for the benefit of their fellow medicals with a board of directors consisting of doctors. In 1925 I suffered from infective endocarditis, pulmonary embolism, and other complications which prevented me from working, and during the whole of this time on the first day of the month I have received a cheque. Had I insured elsewhere under an annual contract I should have been paid for a year, after which the company would not have taken any further risk and it would not have been possible for me to insure again. If all medical and dental students were to insure with this society immediately they are qualified—and the younger they are the smaller is the premium—they will find their troubles lessened, if like myself they contract a prolonged and incurable disease. If the sickness is a short one the benefit will help to pay the locum tenent's fees."

NEW PREPARATIONS

MONOTREAN, which is made by Luitpold-Werk, Munich, and newly put on the market in this country by Medical Laboratories Ltd., 40, Pall Mall, London, S.W.1, is a preparation of papaverine and quinine designed to relieve vertigo. Each tablet weighs 0.2 g. and contains 0.04 g. of papaverine. The remedy is recommended both for Ménière's disease and for giddiness associated with organic lesions; for Ménière's disease the suggested dose is one tablet three times daily after meals for 6-8 weeks, and subsequently one tablet twice a day until the attacks cease. Good results in 41 cases were reported by A. E. Lampé in 1930 (Münch. med. Woch., 1930, lxxvii., 1630) and he noted no unpleasant effects save noises in the ear produced in some cases by quinine at the beginning of treatment. One patient had used the remedy as a preventive daily for six years. Since papaverine is an opium derivative the question of possible addiction arises. The belief expressed in text-books, however, is that this alkaloid does not produce either tolerance or habituation, and its toxicity is low. It is mildly narcotic and analgesic, and relaxes plain muscle, including the arterioles.

ADDRESSES AND ORIGINAL ARTICLES

SOME EPOCHS IN MEDICAL RESEARCH *

BY SIR HENRY DALE

M.D. Camb., F.R.C.P. Lond., SEC. R.S.

DIRECTOR OF THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH

AMONG his many and generous benefactions to the college, which long held a central place in his interest and his devotion, William Harvey, as you know, provided for the delivery of an annual oration "to commemorate all the Benefactors of the College, and to Exhort the Fellows and Members of the College to search and study out the secrets of Nature by way of Experiment." Harvey thus formally bequeathed to us a great tradition, and took care that we should annually be reminded of its meaning and its claim. A Fellow of this college could receive no higher honour than to be called upon thus to commemorate William Harvey himself, as the greatest of our benefactors, and to obey his injunction; and I thank the president for having, in this year, accorded this honour and this duty to me.

A New Method of Increasing Knowledge

We remember with pride that Harvey was lecturing on anatomy to this college during the twelve years which preceded and led up to the publication of his immortal book. It is on record that the transforming conception of the function of the heart, as a pump driving the blood "as it were in a circle," had already taken shape in his mind when his first course of these lectures began. Of the earlier course of development which had led him to the great discovery we know little beyond what he tells us in his book, and there in logical rather than historical order. We may feel certain, however, that the initial incentive to his inquiry was received during his studies in Padua. He tells us, indeed, that the discovery and description of the valves in the veins, by his teacher, Fabricius, acted as a direct stimulus; and there was other knowledge already then available, and waiting only for the central conception with which Harvey was to give it unity and simple meaning. The passage of blood through the lungs, from the right to the left side of the heart, had been clearly put forward in the book of Realdus Columbus, who may have seen it in the earlier tract of Servetus; Cesalpinus had apprehended the meaning of the heart valves, had argued that expansion of an artery with the pulse must be synchronous with the systole of the ventricle, and had even recognised that blood flows from the heart in the systemic arteries and to it in the veins. We might receive the impression that a simple step only was needed, for the discovery that the blood has a continuous and double circulation. My predecessor of two years ago, Sir Thomas Lewis, suggested to us, indeed, that the discovery could not long have been delayed, even had Harvey not made it, and that with the introduction of the microscope it could not have remained concealed. I suspect that, in that opinion, too little influence may have been allowed to the blinding effect of age-long tradition and doctrine, to question which was still an impiety, and which still befogged the minds even of those among Harvey's predecessors

who had most nearly arrived at the truth. I feel no strong conviction that even Malpighi, when the microscope showed him the movement of blood in the capillary vessels, would have known the meaning of what he saw, if Harvey's experiments, presented in a masterly array of argument, had not swept away the doctrine of Galen before the capillaries could be seen. It is clear that Harvey's own teacher, Fabricius, though he saw the valves in the veins and even observed their obstructive effect when the blood was pressed towards the periphery, thought of them only as preventing a too rapid passage, in what still seemed to him a natural direction of the flow. We know, too, that when, after years of experiment, demonstration and argument before this college, Harvey gave his discovery to the world, it found a world unready to accept it, even in those circles which had the same access to knowledge of all that had been done before Harvey. The rare combination was needed of the scientific insight of genius, with a character and a courage of the highest order, to enable Harvey to break through the mists of hallowed error and to walk boldly into the light of a new epoch.

I am in the fullest agreement, however, with Sir Thomas Lewis and with others among my distinguished predecessors, in regarding as Harvey's greatest achievement, not that he made a discovery of such profound and permanent significance, but that he created and displayed for all time the method by which such discovery may be attained and made secure. In the dedication of his book, "*De Motu Cordis*," he lays down the principle of his method—"not from books, but from dissections; not from the positions of philosophers, but from the fabric of nature"; and then, in the book itself, he gives us the supreme example of its application. Again and again in his writings he recurs to this new principle of research, and proclaims his creed with an apostolic fervour. Thus, in his less familiar book on the *Generation of Animals*, "It were disgraceful, therefore," he writes, "with this most spacious and admirable realm of nature before us, and where the reward ever exceeds the promise, did we take the reports of others upon trust, and go on coining crude problems out of these, and on them hanging knotty and captious and petty disputations."

To the men of his day Harvey was preaching a new doctrine, and proclaiming a new method of increasing and securing knowledge. In this, indeed, he moved with the advancing thought of his time, and of the great men with whom he had had contact; for Galileo was a professor in Padua when Harvey studied there, and Francis Bacon was Harvey's patient. To us it may seem now to be a platitude, that science advances by experiment and by direct appeal to Nature, rather than by disputation about what others have observed, or we ourselves have thought and believed. Yet, as Harvey seems to have foreseen, all of us, whether our effort to advance knowledge is made by the bedside or in the laboratory, need still to be reminded of this now familiar truth. The winning of real knowledge by experiment is slow and laborious, and exacts a stern discipline, while speculation offers an easy invitation to the ingenious mind. Theories we must have, to give system to our facts and direction to our experiments; and the temptation is ever present, to the eager experimenter even more, perhaps, than to the quiet observer, to press new facts into the framework of

* The Harveian Oration delivered before the Royal College of Physicians of London on Oct. 18th, 1935.
5852

a plausible theory, and to distrust or to disparage those which refuse to fit easily into a fancied picture. We stand all in daily need of Harvey's exhortation, to approach Nature with clear vision and alert attention, so that we may receive her teaching with free and humble minds.

Harvey and Clinical Research

Sir Thomas Lewis has rightly claimed that Harvey, the physician, was the father not only of physiology but of clinical science. In Harvey's work we may find, indeed, the true beginning of the whole fabric of experimental medicine, of which our own times have witnessed so prodigious a development. No man, with Harvey's passion for inquiry, and with his faculty for patient and precise observation, could have failed to accumulate material of great interest and significance in his practice as a physician. It is sad to think how little of this remains on record for us. In "*De Motu Cordis*" he forsees that "every part of medicine, physiology, pathology, semeiotics, and therapeutics" can be illuminated by the new truth of the circulation which he has declared, and that a field for study has been opened, so vast that his "whole life, perchance, would not suffice for its completion." In his first argumentative pamphlet, addressed to Riolan in defence of the circulation, published in 1649, he still speaks of his intention of publishing his "*Medical Anatomy*," which from his description of its contents might have made him the first of morbid anatomists. Elsewhere, in the essay on Parturition, which is richer than most of his writings in clinical records, he refers to one case as introduced from his "*Medical Observations*." We shall never know how much of Harvey's records of clinical research may have been lost to us by the political robbery and destruction of his papers during the Civil War. Scattered through his published work we find but a sample here and there, as in the clinical experiment introduced, with but little relevance indeed, into a chapter of "*De Generatione*." There Harvey describes a young nobleman who, as the result of fractured ribs followed by suppuration, was left with a permanent, open cavity in his side. At the bottom of this Harvey's exploring fingers encounter the rhythmically protruded apex of the heart, covered only by a layer of "fungous flesh"; so that he can now verify on man, and demonstrate to the King, the correspondence of the apex-beat and of the pulse at the wrist with the systole of the ventricle, in conformity with what experiments on animals had shown him long before; but he can also add the new observation, which no animal experiment could have enabled him to make, that the normal heart is without any sense of touch.

The Genesis of the Royal Society

Harvey was a physician, and approached his problems as such; but he was a man of his own period, or in advance of it, ranging in eager inquiry over the whole animal kingdom, and using everywhere the simple methods of investigation which came within the scope of his training and his equipment. In "*De Motu Cordis*" and again, more definitely, in "*De Generatione*," we find reference to another of his intended publications, which should have dealt with the Causes, Uses, and Organs of Respiration. In the earlier and justly more famous book we find him still accepting the old doctrine, that the function of air in the lungs is to mitigate the heat engendered in the heart; but by the later date he has had a glimpse of a truth which could

not have been clearly seen with the knowledge of his time, and was not to be truly revealed till eleven years after his death. Discussing the need of the newly born infant for air, when once it has breathed, "it is," writes Harvey, "as if the heat were rather enkindled within the foetus than repressed by the influence of air." He makes the suggestion with doubt and hesitation, admitting that it deals with a question of the greatest difficulty. It is no more, indeed, than an inspired guess; but it brings Harvey into another association, to which he belongs as of right, and to which we may feel certain that he would have belonged in fact, had he lived but a few years later. As early as 1645, when Harvey was still attached as physician to Charles the First, a group of men had begun to meet for discussion of the new experimental philosophy, stimulated by the writings of Bacon and by the news of physical discovery coming from Italy. Harvey's "*De Motu Cordis*" must also have been known to them. Later they met in two groups, in London and Oxford; and the group meeting in London included Harvey's close friend Dr. George Ent, while among those meeting in Oxford was another of his friends, Dr. George Bathurst of Trinity College. Bathurst had even shared in Harvey's embryological observations; for Aubrey tells us that Bathurst "had a hen to hatch eggs in his chamber, which they (Harvey and Bathurst) opened daily to see the progress and way of generation."

Harvey, as we know, retired in 1646 to his brother's house; and when, after the Restoration, the groups of experimental philosophers became, in 1662, incorporated as the Royal Society of London by a Charter from the new King, who desired "with a particular grace" to "encourage philosophical studies, especially those which by actual experiments attempt either to shape out a new philosophy or to perfect the old," Harvey had been dead for five years. But the spirit of the men who formed the new Society was that of Harvey, and their activities were explicitly determined by the principle which he had so insistently advocated, and of which his own work had given a shining example. His intimate friend, George Ent, who was his junior by 26 years, was a member of the Royal Society's first Council.

The Meaning of Respiration

The Royal Society, in its early years, may even be regarded as having, in a more particular sense, continued the work which Harvey had begun. Malpighi had seen the blood capillaries before the Society was incorporated, but Leeuwenhoek's much fuller observations on them were made public in a letter to the Royal Society, as were so many of the discoveries which he so amazingly made with his simple microscopes. It was a group of the early Fellows in the Society, including the great Robert Boyle, Robert Hooke, the Society's first curator of experiments, Richard Lower, and John Mayow, who made the first new stride forward in the science of physiology, which Harvey had founded. Harvey, as we have seen, had begun already in 1651 to doubt the doctrine that the function of respiration was to cool the blood, and to suspect that the air in the lungs might even "enkindle" the heat in the body. He himself could have carried the idea no further, but we may imagine how he would have rejoiced, if he could have been with Boyle and his associates, to watch its development in the light of their new discoveries. For, while Harvey's discovery of the circulation was based on the application of simple

mechanical principles to precise anatomy, and on the experimental examination of the working of the heart and the blood-vessels in living animals, the meaning of respiration could only be revealed by a knowledge of the chemistry which Boyle and his followers were newly creating for themselves. It had to be recognised that the function of the respiration involved a process of the same nature as combustion; and neither process could be understood, until the discovery of oxygen had essentially been made. And this, in effect, was what Boyle, Hooke, and Mayow appear to have achieved, though the full significance of their discovery was long lost to sight. Lower, the only physician of the group, who also made important extensions of Harvey's work on the heart, added to the study of respiration the important discovery, which Harvey himself might have made, that it is exposure to the air in the lungs which changes the dark venous into the bright arterial blood; and Hooke gave a demonstration to the Royal Society which Harvey might well have made to the College of Physicians, when he showed that life was maintained with an open chest, when air blown steadily into the trachea was allowed to escape from holes made in the surface of the lungs. But the essential function of the air, and in particular of what they called its "nitro-aerial spirit," in supporting a kind of slow combustion in the body, could only be apprehended by these men who were studying air and its relation to combustion in general, in the light of the new sciences of physics and chemistry, of which they were themselves among the founders.

Separation of Physiology from Clinical Medicine

It seems to me to have been inevitable that, under these conditions, the study of respiration, and with it the centre of progress in physiology, should for the time have passed out of the hands of the physicians, and into those of investigators ranging the whole field of natural philosophy. The divorce from medicine of physiology, especially in this country where Harvey had brought it to birth, not only became nearly complete—more nearly complete, I believe, than it can ever become again—but it persisted for more than a century. And this may have been partly due to the fact that progressive minds in medicine became preoccupied with the systematic task of describing and classifying diseases; but the long persistence, I believe, was due in greater measure to the failure of chemistry to adhere to the principle which Harvey had proclaimed. It seemed to turn its back on the truth which had so nearly emerged from the early experiments of the Royal Society, and followed Stahl, a learned chemist, but a dangerous and speculative theorist, who led it, and much of physiology with it, into the fog of the phlogistic theory. For more than a century progress was retarded and truth was obscured, as the results of experiments were fitted or distorted into this frame of error. It began to be shaken with Black's discovery of carbonic acid; but even Priestly, when he rediscovered oxygen, could only regard it as "dephlogisticated air," and respiration, with putrefaction and combustion, as a "phlogistic process." The experimental genius of Lavoisier was needed to sweep the cloud away, and to let the light shine, which had already been dawning more than a century earlier, so that physiology and medicine could once more go forward with a clear vision; and Lavoisier thus became the greatest physiologist as well as the greatest chemist of his day.

Conditions of Renewed Collaboration

Of the leading actors in this rather sad interlude, Stahl was a physician, as Harvey had been; but Stahl had forsaken Harvey's methods, and relapsed into those which he condemned. I think it can properly be argued, however, that from Boyle to Lavoisier the basal discoveries required for the understanding of respiration had to be made by those who were laying the foundations of physics and chemistry, without any insistent preoccupation with the structure and functions of the human body, in health or in disease.

Already, then, from the very beginning of experimental science, when, as we are apt to think with envy, the whole of the new experimental knowledge could still be assimilated by a single trained intelligence, some division of function began to show itself among the promoters of physiology, according to their way of approach, from the side of medical training or from that of the fundamental sciences. The division has inevitably grown deeper and the lines of cleavage ever more numerous. Such reproduction by fission is common to all the sciences, and is almost a condition of their growth; but, as with all but the lowest organisms, rejuvenescence and renewed vigour of development is dependent on fertilising intercourse, between units which have acquired a relative independence. There are those who see with fear and with regret the extent to which large and actively progressive sections of physiology, and even of pathology, have now loosened, or almost broken for a time, their connexion with the parent medicine, and formed closer alliance with physics, with chemistry, or with other branches of science. I believe the fears to be groundless, and I am sure that the regrets are vain. It would be deplorable, indeed, if there should be any failure in the succession of those who, coming to physiology from the side of medicine, devote themselves to increasing knowledge of the functions of the normal animal or human body as a whole, and make their contribution to the growth of medical knowledge in close coöperation, and even in functional interchange, with those whose centre of activity is in the wards. I see no reason to fear such failure: on the contrary, I think there are many signs of a growing recognition, that both physiology and clinical medicine have still this duty and this need of a more immediate coöperation. But, as at the new birth of experimental science in the seventeenth century, so to-day there are still domains opening to physiology, which can only be explored by men, some of them trained in other disciplines than that of medicine, who must find their fruitful alliances in other fields of progressive scientific knowledge. I have no qualm of doubt, that the result, in the future as in the past, will be ultimately to infuse new life into medicine itself, and to promote its renewed advance, provided only that one condition be fulfilled. And I speak now in warm endorsement of the plea, which Sir Thomas Lewis urged here with such conviction two years ago. The condition is that clinical medicine itself, in the hands of those who devote themselves to the increase of knowledge rather than its application, should remain, and should increasingly become, an experimental science, as Harvey saw it. As science grows, each of its followers must of necessity limit his expert knowledge and special technique to an ever narrowing field; but the condition for stimulating and fertilising contacts is not community of expert equipment, but a common priority of interest in the advancement of scientific knowledge, and a common direct experience

of the method by which that advance can be promoted. Harvey gave the first great example of that method, and wished that we should be exhorted still to follow it. By obedience to that exhortation clinical medicine can remain in full communion with the other departments of experimental science, giving them its full coöperation and taking its full share in the general advance.

"De Generatione Animalium"

Harvey's "*De Motu Cordis*," though its contents changed the face of medicine and opened a new epoch in science, is little more than a pamphlet in length. It may be supposed that, during the years in which he tested and confirmed his facts and interpretations, in lectures to his colleagues, Harvey was sifting his materials and clearing his mind, and was thus able to achieve this masterpiece of compact and orderly presentation, by which the reader is carried with him to a triumphant and irresistible conclusion. Very different in this respect is the other book which he left us, "*De Generatione Animalium*." This contains a wealth of careful and accurate observations, in the two series dealing with the development of the chicken on the successive days of incubation, and with the appearance and development of the foetal deer on successive days after impregnation of the doe or the hind. Harvey's description of the earlier stages of embryogeny, and especially of placentation in the cervidae, for the observation of which his royal master and patient allowed him to have unrivalled opportunity, might, one feels, gain a new interest, if edited and interpreted in the light of the comparative knowledge of these processes, which has been so greatly extended in recent years. Harvey, however, though he could, as always, observe faithfully and give a precise and vivid description of the things and the changes which he saw, lacked for their interpretation all that the microscope began to reveal so soon after his day. And though his description of the origin and development of the chick deals faithfully with the sometimes fantastic errors of his teacher Fabricius and others of his predecessors, it cannot stand with that which Malpighi was to send to the Royal Society some 22 years later, and which remained with remarkably little need of change for another two centuries.

This book, we may feel sure, is not in the form in which Harvey would himself have prepared it for publication. It is long and diffuse, and full of digressions which interrupt the progress of the argument. We know, indeed, from George Ent, that it would not have come to publication at all had his persuasion not prevailed over Harvey's reluctance. Thus we have here presented to us, not the concise account of new observations, and of conclusions directly to be drawn from them, which Harvey in the days of his mind's full vigour might have given us. We have, instead, together with records of brilliant observation, mostly set down long before, the long-drawn and wordy cogitations which had probably accumulated over many years; in particular we have, at each stage, long discussions as to the points on which Aristotle was already right, or as to those on which Fabricius can be shown to have gone astray. Harvey was an ageing man, tired with the controversies in which he had been involved by "*De Motu Cordis*," unwilling to publish more, and depressed by the thought that his work on reproduction was left permanently incomplete by the loss of his observations on insects. We may be very glad, however, that Ent overcame his scruples; for

this book not only gives us further insight into Harvey's method, when he "addressed Nature herself," and "consulted his proper senses," but allows us also to see into what vague and fruitless speculations even he could wander, far beyond the facts available to his observation, when he forsook his own precepts. Harvey, with no microscope, could have no knowledge of spermatozoa, though it is curious that he should have missed the follicles and corpora lutea of the mammalian ovary. Like his predecessors, he seems still to regard the ovary as a kind of female testis, but he rejects the view that the male and the female seed mingled in the uterus, and there gave rise to the ovum. He knows, of course, that the hen can produce ova without fertilisation by the male. Not finding the semen in the uterus after coitus, he denies that it penetrates so far. For him the semen exerts a mysterious fertilising influence on the whole female organism, under the stimulus of which the uterus conceives a fertile ovum, as the brain conceives an idea. He seems almost to allow himself to be misled by a metaphor; for, having seen waves of contraction passing over the uterus of a recently impregnated deer, he even wonders whether the brain would show such movement, if we could watch it in the act of conception.

Some discussion has arisen with regard to Harvey's views, as indicated in various passages of this remarkable book, as to the possibility of spontaneous generation. It is, indeed, not easy to be certain as to his belief. On the title-page and early in the text he clearly states that "all animals . . . are produced from ova." Later, in the same chapter, we find him stating: "Even the creatures that arise spontaneously are called automatic, not because they spring from putrefaction, but because they have their origin from accident, the spontaneous act of nature, and are equivocally engendered, as it is said, proceeding from parents unlike themselves." Here he seems to believe that, though the egg must always be the first stage, it may in some cases arise spontaneously, or from parents of a different species. Later in the book, however, we find another passage, written perhaps at a later date, which, if taken by itself, would suggest that Harvey had reached a conclusion much further in advance of the knowledge of his day. "But on these points," he writes, "we shall say more when we show that many animals, especially insects, arise and are propagated from elements or seeds so small as to be invisible (like atoms flying in the air), scattered and dispersed here and there by the winds; and yet these animals are supposed to have arisen spontaneously, or from decomposition, because their ova are nowhere to be found." We are left wondering what we may have lost by the destruction of Harvey's records of his observations on the generation of insects; how they might have related his experiments to those of his contemporary Francesco Redi; and what basis of observation they might have shown us for this remarkable passage. Harvey, we must remember, had no knowledge of any animals, or living things, too small for detection by his unaided vision. But this conception, even in relation to the living things which he knew, is much in advance of his age, and seems to link him in thought, across the coming centuries, with Spallanzani, and even with Pasteur and Tyndall.

Research of To-day

It is customary on this occasion to review some recent phases of active experimental development

in the field of the medical sciences. We could pay no more fitting tribute to the memory of the founder of experimental medicine. The task of selecting items for such mention, and especially of associating them with the activities of particular men, will probably become year by year less easy. It becomes indeed ever more difficult for any investigator to scrutinise and to appraise even those published observations and experimental records which are related to his own special field of work. It begins to be the rule rather than the exception for some new and definite advance to be announced almost simultaneously from more than one laboratory, and often from more than one country. The position may well look different in historical retrospect; but to us who live amid this urgency of accumulation, it must seem unlikely that a new epoch will ever again be opened by a Harvey or a Darwin, sifting and testing his evidence for patient decades, before he gives his theory to the world. Meanwhile we can try to distinguish tendencies, and lines of more rapid development, promoted by the activities of many, which the future may recognise, perhaps, as epochs dating from our own time.

ULTRAMICROSCOPIC VIRUSES

We date the beginning of the great epoch of bacteriology, dealing with organisms which the ordinary microscope revealed, from the work of Louis Pasteur and Robert Koch. Harvey had no knowledge of living beings below the limits of unaided visibility; but he had only been dead twenty years when Leeuwenhoek, in one of his letters to the Royal Society, first described and even recognisably figured bacteria, as seen with his simple lenses. Two further centuries passed, however, before Koch was able to give the first completed identification of a bacillus as the specific cause of a disease. When, after a period of progressive triumph, bacteriology still failed to reveal the causes of some of the most familiar and deadly among the infectious diseases, there came in our own time the intensive study of a further order of living, infective agents, below the range of ordinary microscopical vision. It is unlikely that the future will identify any outstanding names with what may be the beginning of another epoch as important to medicine as that of bacteriology, concerned with the viruses still called "ultramicroscopic" or "filterable"; though special microscopical methods have already rendered many of them visible, and all can be stopped, and even differentially separated, by filters of an adequate and accurately graded fineness. We associate the names of Ivanovski and of Beijerinck with early discoveries of such a virus as the cause of a plant disease, and those of Loeffler and Frosch in a similar sense with the virus causing the foot-and-mouth diseases of cattle. But the general advance in this field, which did not begin until a quarter of a century later, has been on a wide front, and investigators in many laboratories of many lands are engaged in it. In rapid succession the agents responsible for infectious diseases, which bacteriology had left as unsolved problems, are being identified as belonging to this group, which but a few years ago seemed so inaccessible to further research. My colleague, C. H. Andrewes, in his Oliver Sharpey lectures of 1934, discussed before this College the many respects in which conformity to this type is shown by the infective agents which transmit certain tumours in experimental inoculation. One of the recent additions to the general list of diseases transmitted by viruses, and one which has excited interest

in circles beyond that of medicine, is epidemic influenza, for the study of which by my colleagues, Laidlaw, Andrewes, and Smith, the earlier work of Laidlaw and Dunkin on dog distemper had provided some ground of experience, and had brought to notice a suitable subject of experiment, in the ferret. Further advance in the study of this, and of many other virus infections, is dependent not only on the provision of opportunity by Nature and by clinical medicine, but also on the development of new methods, which is in active progress in many laboratories. New principles of immunity, for which bacterial immunology has given at best imperfect analogies, are coming into view. The greatest difficulties of conception, however, are those connected with the dimensions of the infective units of the different members of a series showing so many points of uniformity in their general behaviour; for these units are, at the upper end of the scale, just visible by ordinary microscopy, with the appearance of very small cocci; while, at the lower end, the units of such viruses as those of foot-and-mouth disease and poliomyelitis appear to be of comparable dimensions to the molecules of certain complex proteins. Here, if the data of measurement have been rightly interpreted, we seem, through a continuous series, to pass from definite though very minute organisms to a borderland between organisation and colloidal dispersion, where biology and physical chemistry must, perhaps, join hands in interpretation of a new order of vital phenomena. It may be noted that, quite recently, confirmation has been given of a previous claim to have obtained the virus of a plant disease in the form of protein crystals.

AN EPOCH OF CHEMISTRY IN MEDICINE AND BIOLOGY

If I were asked to name a prevailing tendency of the present time, in medical, and indeed in a wider range of biological research, I should refer to the rapidly increasing dominance of chemical methods and chemical ideas. Within the memory of many of us, organic chemistry had still but a small and precarious footing in this domain. To-day, not only has biochemistry firmly established its claim to separate recognition and enrolled a growing army of investigators, but physiology, pathology, immunology, even embryology, are increasingly permeated by chemical ideas and chemical methods, which are yielding a surprising harvest of discovery, in fields which till recently seemed beyond hope of such cultivation. I can permit myself to choose but a few examples.

HORMONES

Research on the hormones is one of the directions in which, at the moment, chemistry can show a record of the most rapid advance and of unforeseen achievement. Twenty years ago, of the hormones then recognised, adrenaline alone had been chemically identified and made by synthesis. Of the others, only thyroxine, on account of its great stability, seemed possibly accessible to structural chemistry; though few could have expected that its structure would so soon be determined and its synthesis achieved. Secretin and the active constituents of the pituitary posterior lobe had been obtained in stable, though highly impure solutions; but for the other ductless glands, even the formation and secretion of hormones by them was a matter of inference rather than direct demonstration. There seemed little likelihood that such hormones would ever be extracted, and the possibility of their isolation for chemical study seemed too remote for consideration.

I believe that the successful preparation of insulin, by Banting and Best, had an influence far beyond that due to its immediate importance for medicine and for the understanding of carbohydrate metabolism, in that it aroused a new spirit of enterprise and optimism with regard to the possibility of obtaining other hormones, which had seemed equally intangible. Insulin itself, being of protein nature, still presents a difficult problem to the structural chemist; but it has been crystallised, and the interesting discovery has now been made (Scott) that the crystals are insulin in combination with metallic ions, normally those of zinc. Since insulin was first prepared methods have been found for extracting the hormone of the parathyroid glands and that of the suprarenal cortex, and it seems probable that the latter has now been obtained in a pure, crystalline form in more than one centre.

A series of hormones from the gonads have, in the space of a few years, been isolated, identified, and in more than one case even made artificially by partial synthesis. These hormones determine secondary sexual characters and cycles of sexual activity; they provide for implantation of the fertilised ovum, and for the development of the placenta and the active mammary gland. The generation which immediately followed Harvey saw the recognition of the ovarian follicles by De Graaf and the description of the spermatozoa by Leeuwenhoek; but even by the end of the nineteenth century such problems as the causes determining the development of accessory reproductive organs, and the nature and causation of the sexual cycles in different animals, had only been touched by the investigations of such lone pioneers as the late Walter Heape. And even till the second decade of the present century, the work of Heape, and of F. H. A. Marshall whom the college to-day honours with its Baly medal, stood almost isolated in this country in its bold attack on what seemed the almost impenetrable tangle of sexual physiology. To-day we are already in clear sight of the ascription of each phase of the female sexual cycle to the action of a separate, chemically identified ovarian hormone; a hormone from a ripened ovarian follicle being responsible for the oestrus in which the uterus is prepared and sensitised for its function, while another, from the corpus luteum, in due course brings about the endometrial hypertrophy, which provides for implantation of a fertilised ovum, or, failing it, terminates in the menstrual breakdown. There are yet many complexities to be unravelled; but these two ovarian hormones, as also a testicular hormone, are already substances of known chemical structure; and the luteal and male hormones have been artificially prepared from different inert sterols. In the case of the oestrogenic and of the male hormone, chemistry can now indicate, in each case, the precise structure of a less active form excreted in the urine, and its relation to that of a more active form obtained direct from the respective gonad, and presumably representing the true, effective hormone.

Behind this immediate control, moreover, and determining the development and successive phases of activity of the gonads themselves, is the anterior lobe of the pituitary body, with its complex of hormones, still beyond the reach of structural chemistry, but ever growing in apparent number, with the progressive recognition of the multiple functions of this little gland. The breath-taking rapidity of experimental progress in this particular field may be inducing a too facile postulation of a new hormone, to account for each new set of phenomena observed; but if observation is accurate and uncoloured by preconception,

the true meaning will emerge in due course. In any case it is clear that the anterior pituitary lobe exerts some kind of hormonal control over the development and activities of practically every other endocrine organ, and therewith over almost every phase of growth and of metabolism. Even more mysterious in their meaning are the recent observations of Collip and his co-workers, showing that some of these hormones, on continued artificial injection, provoke in the recipient a resistance to their own actions, which its blood-serum can then transmit to another animal.

We have noted that such of the sex hormones as have been isolated have points of common structure with the sterols, and can, in some cases, be prepared by chemical modifications from members of this group. This brings them into a curious relationship with other substances, also structurally related to the sterols, and possessing intense biological activities of widely different kinds—the antirachitic vitamin D, the cancer-producing constituents of tar, and the heart-stimulating glucosides of the digitalis group. There is evidence, again, that the organisation of the cells of the early embryo into the characteristic foetal structures is effected by a chemical stimulus, and that the substance concerned also partakes of the molecular pattern common to the sterols, and to so many substances of intense but apparently unrelated activities.

VITAMINS

In the group of the vitamins, which so recently might have been regarded as intangible traces of unstable and probably highly complicated substances, chemistry has found in recent years so successful an application, that three vitamins have already been chemically isolated, including the vitamin D already mentioned, together with the natural precursor of another, and one has already been made by artificial synthesis. In some ways comparable to the action of the vitamins is that newly discovered for choline. The recent work of Best and his co-workers seems to show that the presence of choline, or of the allied betaine, in very small quantities in the diet, is in some way essential for the maintenance of a normal adjustment between the deposition of fat in the liver and its mobilisation from that organ.

OTHER APPLICATIONS OF CHEMICAL METHODS AND IDEAS

Many other examples could be quoted of this increasingly prevalent and successful application of chemical methods, to problems in all departments of medical science, which even recently seemed to be beyond the reach of such attack. Thus, structural chemistry already has its place in immunology and begins to reveal the nature of antigenic specificity. The late Dr. James Collier made reference here last year to the evidence which is being obtained by my colleagues and myself of the intervention of known chemical stimulants, and in particular acetylcholine, in the transmission of the effects of nervous impulses across the gap between the ending of a nerve-fibre and an effector cell or another neurone, apparently throughout the peripheral nervous system. The chemical changes in a muscle accompanying its contraction seemed but a few years ago to be adequately comprised in a cycle of cleavage and resynthesis between carbohydrate and lactic acid. They are now revealed as a highly complicated chain of linked reactions, involving creatine, adenylic acid, and phosphoric acid, in addition to carbohydrates; and

the complexity still grows. Sir Thomas Lewis and his co-workers, whose earlier experiments on the skin vessels of man brought evidence of the release of a chemical substance as the cause of their reactions to injury or irritation of the epidermis, thus making contact with our laboratory investigations on the occurrence and actions of histamine, now trace the pain caused by ischaemia of a muscle similarly to a chemical source.

Conclusions

If we allow ourselves to pause a little and to ponder, standing aloof for a moment from the insistent quest for new experimental data, with its growing multitude of eager followers, we may begin to ask whether it is leading us. We have only to look back to the beginning of this century to realise how all aspects of medicine—diagnosis, treatment, and prevention—have been involved in, and in some directions transformed by the change which has been taking place. But are we really at the beginning of a new, great epoch, or merely involved in one of which the end can already be seen from afar? We can now speak familiarly of the chemical structure, and even the artificial synthesis, of hormones and vitamins of which the very existence was but recently a mere presumption from observed effects, but we have no basis even for speculation as to why a precise structure endows a substance with an effect so potent and often so complex. We can identify in the body the types of cell which are specifically sensitive to acetylcholine, and we can find evidence that impulses, passing down nerve-fibres which end in contact with these cells, excite or inhibit their activity by releasing that substance; we can even make an estimate of the number of molecules of acetylcholine released by a single impulse at a single ganglionic synapse; but we are no nearer to a conception of the meaning of a specific sensitiveness to a substance having that structure, or as to why its presence should augment the activity of one type of cell or inhibit that of another. The complex changes accompanying a muscular contraction are known in much greater detail than those of any other kind of functional metabolism; but there is yet no knowledge clearly relating these changes, or any part of them, to the mechanical event of the contraction. Are we witnessing the early stages of a major advance, in which a finer physical conception of the structure of living matter will ultimately give order and meaning to the knowledge, now so rapidly accumulating, of the chemical changes which accompany vital activities, and of the chemical substances which so mysteriously condition or control their occurrence? Or will physiology find itself brought early to a halt in the line of its present advance, baffled by a complexity which its methods have revealed, but which they cannot yet begin to resolve? None of us, I think, can answer such questions. We must be content to follow patiently what clues we find, and to go forward in the faith of Harvey, that "Nature herself is to be addressed; the paths she shows us are to be boldly trodden; for thus, and whilst we consult our proper senses, from lower advancing to higher levels, shall we penetrate at length into the heart of her mystery."

DEVONSHIRE ROYAL HOSPITAL, BUXTON.—During the year 1904 sufferers from rheumatic diseases have been admitted to this hospital, and the ordinary income has shown an increase of £531 and the expenditure a decrease of £374. The erection of a new wing is under consideration.

AGRANULOCYTOSIS

MENINGITIC SYMPTOMS WITH CHANGES IN THE CEREBRO-SPINAL FLUID IN A CASE OF RELAPSING TYPE

By SIR KENNETH GOADBY, K.B.E., M.R.C.S. Eng., D.P.H.

MEDICAL REFEREE FOR INDUSTRIAL DISEASES, HOME OFFICE; LECTURER ON BACTERIOLOGY OF THE MOUTH, UNIVERSITY COLLEGE HOSPITAL DENTAL DEPARTMENT; AND

C. WORSTER-DROUGHT, M.D. Camb., F.R.C.P. Lond.

PHYSICIAN TO THE METROPOLITAN HOSPITAL AND TO THE WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM, LONDON:

With Report on the Cerebro-spinal Fluid by

W. E. CARNEGIE DICKSON, M.D., F.R.C.P. Edin.

DIRECTOR OF THE PATHOLOGICAL DEPARTMENT, WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM

THE case to be described is of particular interest in that we can find no previous record of the occurrence of meningitic symptoms, nor of the results of an examination of the cerebro-spinal fluid, in a case of agranulocytosis. Opportunity was also afforded for chemical examination and histological examination of the blood during the prodromal period of a relapse.

The diagnosis of agranulocytosis was made during an illness which started in April, 1934, with vomiting, pyrexia, and ulceration of the gums. After a few weeks the more acute symptoms yielded to injections of Pentnucleotide, but there were subsequent relapses in May, June, September, and December, 1934, and a severe one towards the end of February, 1935. It was during this last attack that definite meningitic symptoms—drowsiness, neck rigidity, and Kernig's sign—were first observed. Each of the previous relapses had been ushered in with pyrexia, languor, and prostration, but no physical signs indicating involvement of the nervous system were detected. During each relapse the granulocytes fell to a very low level; the spleen was palpable and abnormal signs—dullness and crepitations—appeared at the base of the left lung. At no time during the entire course was *Bacillus fusiformis* or Vincent's spirilla detected in films from the ulcers of gums, throat, or tongue.

CASE RECORDS

The patient was a stout and rather florid woman of 60. The previous medical history was unimportant; she had had chicken-pox and measles while a child, and at the age of 30 "congestion of the lungs." No definite illness had occurred since, but she had suffered intermittently from flatulence, dyspepsia, and constipation, and she showed menopausal obesity. In October, 1933, she developed pneumonia at the base of the left lung with a temperature of 104° F., and was treated with injections of antipneumococcal serum. Recovery was rapid. There was no history of taking amidopyrin.

FIRST ATTACK

During the latter part of April, 1934, the patient had an attack of vomiting (which she attributed to eating oysters) with severe occipital headache, abdominal pain, and constipation. The abdominal symptoms and headache persisted but the temperature remained below 98.4° F.; the pulse-rate varied from 65 to 80. The urine was sterile; no organisms of the typhoid-paratyphoid group were found but agglutination to paratyphoid C was positive up to 1/1600. The spleen was enlarged and palpable; there was dullness and fine

crepitations at the base of the left lung; the abdomen was distended, and the liver edge palpable and tender but there was no jaundice. No rose spots were found, but the skin of the abdomen and thighs was generally affected with a miliaria which could be felt better than seen. On April 28th vomiting recommenced and the temperature rose to 100.6° F. but fell to normal on April 30th. On May 2nd the temperature rose to 101° F., with general drowsiness and increased headache. The throat was oedematous but not ulcerated, the gum margins bright red and injected also not ulcerated. The cranial nerves and optic discs were normal; the knee-jerks normal and the plantar reflexes flexor; the abdominal reflexes present but weak; arm-jerks present; no paresis or hyperæsthesia. The liver was still tender on palpation and enlarged; the spleen enlarged, palpable, and tender; there were no crepitations at the base of the lung.

On May 4th a blood examination showed 5,400,000 red cells and 2200 white cells, of which only 3 per cent. (66) were granulocytes; Arneth's count showed 3 per cent. trilobed nuclear polymorph cells and no horseshoe or rod nuclear cells; 76 per cent. small lymphocytes, 20 per cent. large lymphocytes, and 0.5 per cent. eosinophils. The hemoglobin was 70 per cent., giving a colour-index of 0.6. The sedimentation-rate was 40 in one hour.

Blood chemistry: non-protein nitrogen 34 mg., urea 7.9 mg., uric acid 4.3 mg., phosphorus 3.5 mg., and calcium 9.2 mg. per 100 c.cm.; sugar 0.065 per cent.; van den Bergh reaction 1/4 unit; alkali reserve 58.3.

A diagnosis of agranulocytosis was made and pent-nucleotide administered intramuscularly. After the second injection the temperature fell to normal and remained so for a week; two small rises occurred which reacted at once to injections of pentnucleotide. A large ulcer which had appeared on the left side of the tongue rapidly cleared up, the abdominal symptoms subsided, appetite returned, and the patient's general condition rapidly improved.

FIRST RELAPSE

At the end of May, 1934, the first relapse occurred, being ushered in by the same train of symptoms—i.e., increasing drowsiness, vomiting of bile-stained fluid which contained no free hydrochloric acid, occipital and vertical headache. The gingivitis, confined to the gum margins, recurred with ulceration affecting the gum round the two upper central incisors and extending half an inch from the teeth. Films from the gingivitis and the sloughing area failed to demonstrate Vincent's *B. fusiformis* and spirochæte; there were, however, a considerable number of spirochætal forms present identified as *Spirochæta macrodentium* and *microdentium*, with numerous long, thin thread forms of *B. necrosis*. The

breath was exceptionally foul. The clinical appearance of the ulceration differed from the characteristic ulceration of Vincent's angina; it was much less friable, of a hard leathery consistency, and not surrounded with the usual bright injected area seen in Vincent's ulceration.

Under treatment with injections of 10 c.cm. pent-nucleotide daily, the patient's condition gradually improved and on May 14th the granulocytes had risen to 34 per cent.

SECOND RELAPSE

The second relapse began in June, again with short preliminary vomiting, prostration, and ulceration of the gums, very furred tongue, and later enlarged cervical glands, palpable and tender spleen and liver-edge, and minute nodular urticaria. The granulocytes again fell to 3.5 per cent. with total white cells 2800 per c.mm.; small lymphocytes 58.5 and large lymphocytes 38 per cent., no eosinophils being detected. Subsequent blood counts yielded 1 per cent. eosinophils with little change in the relative proportion of small lymphocytes and large lymphocytes. Again under treatment with pentnucleotide, the patient's condition improved with a rise in the granulocytes to 23 per cent. on July 24th (Fig. 1).

During the early part of the relapse, daily injections of 10 c.cm. of a preparation of manganese nucleotide was tried but without influence on the temperature, clinical condition or blood count; six injections were administered. Daily injections of pentnucleotide were therefore resumed, and after the third injection the temperature again fell to normal, the general condition slowly improving. The mouth ulceration proved most intractable and eventually penetrated so deeply that the two upper incisor teeth were separated from their attachments and were extracted. The febrile period of this relapse lasted for twenty-four days. During the early part of the febrile period, the pulse-rate was increased to 106–112 with a temperature of 102°–103° F., but the pulse-rate fell to 90–96 six days before the defervescence and remained at 84–90 for three weeks after the temperature had become normal. By August the patient had sufficiently recovered to go away to the seaside.

THIRD RELAPSE

At the end of September there was a short febrile period ushered in by the same symptoms of drowsiness and languor, but passing off in a few days. The blood was not examined on this occasion. There was no mouth ulceration or marginal gingivitis.

FOURTH RELAPSE

In the beginning of December another relapse occurred with the same prodromal symptoms of increasing lassitude, drowsiness, and an

FIG. 1.—Course of blood counts. A = total red cells (millions per c.mm.); B = total white cells (thousands); and C = total granulocytes (thousands).

attack of vomiting, again attributed by the patient to unsound food. The vomit, as well as all subsequent ones, contained no free hydrochloric acid; granulocytes were entirely absent from the blood. On Dec. 14th a blood count showed: red blood-cells, 4,600,000; white cells, 3900; hemoglobin 60 per cent.; colour-index, 0.6. Arneth count: polymorphonuclears, 0; small lymphocytes, 74 per cent.; large lymphocytes, 25 per cent. A Price-Jones curve of the erythrocytes gave a diameter curve within normal limits.

Blood chemistry: non-protein nitrogen 31 mg., urea 39 mg., uric acid 6 mg., calcium 9.3 mg., and chlorides 0.390 per 100 c.cm.; urea-concentration factor, 94; urinary

FIG. 2.—Lange's colloidal gold reaction. The black line (0) shows the patient's reaction. Typical illustrative curves (for comparison) are: (1) meningeal field, (2) paretic field, (3) luetic field, (4) normal control, and (5) control with cerebro-spinal fluid containing 0.06 per cent. total protein, but not due to syphilis or disseminated sclerosis.

urea nitrogen, 92 per cent. (urea 3.6 per cent.). Sedimentation-rate 50 per cent. in one hour; van den Bergh $\frac{1}{2}$ unit.

The same clinical signs were present as on previous occasions: enlarged and tender spleen, crepitations at left base, distended abdomen, enlarged and tender liver, minute nodular skin rash. The reflexes were unaltered. The fundi were normal. A large ulcer appeared on the lower lip and the gingivitis returned. The throat was oedematous but not ulcerated; there was mild cervical adenitis.

Pentnucleotide was again injected intramuscularly in 10 c.cm. doses daily and by Dec. 21st the pyrexia had subsided. The blood count gave 5,600,000 red blood cells; hæmoglobin, 75 per cent.; 4297 white blood-cells; granulocytes, 10 per cent. (420); small lymphocytes, 70 per cent.; and large lymphocytes, 20 per cent. By the middle of January the general condition had greatly improved although the state of the heart gave rise to some anxiety—a short, blowing tricuspid bruit developed with canter rhythm. Blood pressure 135/70, pulse 78.

Quantitative urinary examination: output of 1780 c.cm., specific gravity 1011; urea 22 g.; uric acid, 0.346 g.; chlorides, 0.5 g.; phosphates, 2.45 g.; creatinine, 1.7 g.; ammonia, 0.36 g. Nitrogen distribution was within normal limits; 83.5 per cent. urea, 4.9 per cent. creatinine, 1.6 per cent. ammonia nitrogen (low), and 9.1 per cent. residual nitrogen. There was no bile, acetone, sugar, albumin, casts, nor abnormal crystals. A second examination two days later gave almost identical results.

The patient was sufficiently recovered to sit up. The daily injections of pentnucleotide were discontinued and sodium cinnamate (2 c.cm.) injections of 20 per cent. solution given. Hepatex and Radiostoleum were given by the mouth. The blood count improved and the granulocytes rose to 1100 out of 4000 total white cells. Pentnucleotide was given once a week.

FIFTH RELAPSE

The afebrile period continued until Feb. 4th when an attack of vomiting associated with increasing languor and somnolence set in; the temperature rose to 101.5° F., with pulse-rate 100, but fell in 48 hours to normal. The spleen was again palpable and tender; crepitations appeared at the left base; there was severe vertical and occipital headache with intense drowsiness, and a decrease in urine, which now contained a considerable amount of bile. The vomit was bile-stained and contained no hydrochloric acid. Icterus was apparent.

Blood enumeration on Feb. 5th gave 3,800,000 red blood-cells and 936 white cells. Differential count:

60 per cent. granulocytes, 26 per cent. small lymphocytes, 12 per cent. large lymphocytes, hæmoglobin 50 per cent.

Blood chemistry: non-protein nitrogen 32 mg., urea 10 mg., uric acid 6.2 mg., phosphorus 3.8 mg., and calcium 9.2 mg. per 100 c.cm.; sugar 0.07 per cent.; van den Bergh 2 units; sedimentation-rate 50 per cent. in one hour. Urea-concentration factor, 261; urinary urea nitrogen, 84 per cent. The urea clearance was highly active, there were no abnormal constituents in the urine other than bile and bile salts.

On Feb. 10th, again about a week after the prodromal lassitude and vomiting, the temperature began to rise. During this, the most serious of all the relapses, the fever, instead of the continued type of former attacks, was of the remittent septic type alternating from 103° F. to 99° F. On Feb. 13th, three days after the onset of the fever, two large ulcers appeared, one on either side of the tip of the tongue, with indurated base, yellowish leathery sloughs and extremely painful. The bacteriological characters were similar to the previous ulcers—spirochaetes of mouth type, no fusiform bacilli, numerous long, slender thread forms. The granulocytes practically disappeared from Feb. 13th to 28th. Between these dates four blood counts were made, the granulocytes being 480, 100, 100, 90 (see Fig. 1).

A large indurated area appeared on one buttock near the site of one of the pentnucleotide injections; on incision a little blood and pus escaped. A bacteriological examination gave *Staphylococcus aureus* and *Streptococcus mitis*. There were no spirochaetes nor anaerobic organisms present. The abscess healed normally but the incision and drainage had no perceptible influence on the temperature fluctuations.

On Feb. 13th Dr. H. L. Tidy saw the case in consultation and advised blood transfusion; this was carried out on the 15th, a pint of citrated blood being administered intravenously. There was a good deal of immediate reaction with cerebral excitement lasting about an hour but the general condition improved during the next four days with a well-defined drop in the fever. Six days later the pyrexia had assumed the previous remittent type. There was no icterus or bile in the urine. The abdominal distension, enlargement of the spleen and liver, occipital headache, and drowsiness increased; the patient was roused only with difficulty. In spite of continued pentnucleotide injections she became progressively worse and the temperature rose towards 103° F. on Feb. 23rd with the onset of meningitic symptoms. The granulocytes were only 0.5 per cent.; small lymphocytes, 81 per cent.; large lymphocytes, 14 per cent. The total

white cells were 2000; the red cells, 4,600,000; hæmoglobin, 40 per cent.

On Feb. 24th, when the patient was first seen by one of us (C. W.-D.), she was very drowsy and appeared stuporose most of the day but could be roused with difficulty; she then complained of some pain in the neck and occipital region. Temp., 102° F.; pulse, 118; resps. 40. Pupils were moderate in size, equal and reacted normally. Fundi normal. Tongue very furred with slight ulceration. Cranial nerves normal. Moderate neck rigidity; head could not be flexed beyond the vertical line of the body. Kernig's sign positive on both sides. Arm-jerks slight and equal. Knee- and ankle-jerks absent. Plantars flexor. Abdominal reflexes sluggish and equal. Spleen palpable but not the liver. A few crepitations heard at the base of the left lung.

Lumbar puncture was performed. The cerebro-spinal fluid was under slight pressure and was clear to the naked eye. After the removal of 15 c.cm. of cerebro-spinal fluid drowsiness improved, the pulse-rate fell to 80, and the respirations to 32. Dr. Carnegie Dickson carried out an examination of the cerebro-spinal fluid and reported as follows:—

Cerebro-spinal fluid.—Naked eye: clear, colourless, and limpid fluid with no trace of blood or turbidity. Cells: 2 cells per c.mm.; in films of the centrifuged deposit, they were almost all small lymphocytes with only a very occasional slightly larger mononuclear cell; no polymorph or plasma cells seen. Total protein: 0.06 per cent. Globulin: a trace in excess with Pandey's phenol test; saturated ammonium sulphate, both in the ring and shake tests, gave only the faintest detectable trace of globulin. Chlorides: 0.732 per cent. (normal). Sugar: equal parts of the cerebro-spinal fluid and a 1 in 10 dilution of Fehling's solution gave "normal" reduction, and by MacLean's method the amount present was found to be 0.056 per cent. Lange's colloidal gold reaction: 5555432100. (Paretic type of curve.) (Fig. 2.) Wassermann reaction completely negative. Kahn flocculation test completely negative.

There was, therefore, a moderate but distinct increase in the total protein content, a trace of globulin, and a Lange curve of the paretic type.

At this time the granulocytes were only 4 per cent. with total white cells 2700 per c.cm. (Feb. 23rd); and granulocytes 3 per cent. with 3300 white cells per c.cm. (Feb. 25th). The red cells averaged 4,696,000, with Hb. 78 per cent.

Following the removal of the cerebro-spinal fluid, the patient's condition showed some improvement as regards drowsiness and stupor and the neck rigidity and Kernig's sign gradually passed off. The pyrexia continued with exacerbations and remissions until the beginning of April when a slow defervescence occurred. The pentanucleotide was continued, but in addition Acetylarsan was given by subcutaneous injection. The gradual rise in the total white cell count appears to have coincided with its administration. Nausea and vomiting occurred sporadically (free HCl was absent) until defervescence was established. By the end of May the patient had sufficiently recovered to go out for drives, and on May 25th an electrocardiogram was taken which showed the characters of myocardial impairment.

No further relapse has occurred; the patient is convalescing at the seaside, and is leading a normal but restricted existence. On July 30th the blood count showed 4,400,000 red blood-cells; hæmoglobin, 98 per cent.; 5500 white cells; granulocytes, 32 per cent.; small lymphocytes, 33 per cent.; large lymphocytes, 34 per cent.

DISCUSSION

The results of the cerebro-spinal fluid examination in this case are noteworthy in that the Lange reaction of marked "paretic" type, with slight but distinct increase in the total protein and a trace of globulin, exactly resembles the changes found in the majority of cases of disseminated sclerosis. This result suggests a chronic infection of the central nervous system involving actual nervous tissue rather than the meninges only. In both diseases—disseminated

sclerosis and agranulocytosis—an infecting agent is suspected but there is still doubt as to whether the organism is a filtrable virus or a spirochæte.

Certain other features are also of special interest. The series of five relapses, each ushered in with the same train of symptoms—a mild pyrexial attack of twenty-four hours' duration with vomiting and gradually developing lassitude for about a week, after which a mild degree of continued pyrexia supervened, followed four or five days later by development of mouth ulceration and subsequent mild cervical adenitis; total leucopenia with extreme diminution of granulocytes, the red cell count remaining little affected and with no alteration in average diameter. The involvement of the spleen and liver is also noteworthy, but there was no icterus excepting in the last and most severe relapse. It is also somewhat interesting to observe that in the last relapse, which occurred while the patient was under direct observation, the clinical symptoms preceded the fall in granulocytes but the total white cell count fell sharply, which agrees with the observations of Jackson and Parker.¹

The meningitic syndrome developed only during the last relapse, although headache and drowsiness were pronounced symptoms in each relapse and the patient's family observed the gradual onset of lassitude which preceded the actual prodromal symptoms. The rapid sedimentation-rate, low blood calcium, and high lymphocyte count are also special features of the case. The blood chemistry is mainly within normal variation with the exception of the calcium content.

Of the cases reported by Donald Hall,² some developed a swinging temperature; in others the pyrexia was of the pneumonic type; in one case *B. abortus* infection was suspected and in another the possibility of typhoid was considered. In the present case agglutination with paratyphoid C was positive to 1/1600, and with the history of vomiting after oysters was somewhat confusing. In Hall's Case 2 the patient had a relapse in which she died. No history of amidopyrin or allied drugs was ascertainable in our case as in those reported by Plum.³ Blackie⁴ reports a case of agranulocytosis complicating typhoid fever. Fisher's case⁵ apparently began with buccal infection, whereas our patient only developed the mouth symptoms after the actual onset of the disease. The use of an arsenic compound in addition to the pentanucleotide is of some importance in bringing about improvement in the blood picture, as is the failure of the manganese nucleotide to influence the blood count.

Throughout her illness the patient had been under the immediate care of Dr. Roberts Harris to whom we are indebted for drawing our attention to the case and for all facilities for investigation.

TREHERBERT HOSPITAL.—The committee of this hospital are proposing to add a sunlight ward at a cost of £3000 to the female wards. The hospital was built in 1928 at a cost of £32,000, of which £15,000 was provided by the Miners' Welfare Fund committee and a similar amount by the workmen of the area.

APPENDICITIS IN THE AGED

By HERMON TAYLOR, M.D., M.Chir. Camb.,
F.R.C.S. Eng.

FIRST ASSISTANT TO A SURGICAL UNIT, LONDON HOSPITAL.

Of the thousand cases of acute appendicitis admitted each year to the London Hospital, $1\frac{1}{2}$ per cent.—about one case in three weeks—are over sixty years of age. It has been my duty to operate on a number of these cases, and my observations, together with the results of treatment in 110 cases collected from the hospital records during the last seven years, have led me to modify in these old patients the treatment so successfully applied to younger cases.

Both the patient and the course of the disease are different. Not only is the subject a poor operation "risk" demanding the minimum of manipulation and anaesthesia, but the appendix itself is almost always gangrenous or about to become so. In young people there is a striking variability in the actual condition of the "acute appendix," due to the exaggerated effect on its blood-supply of the twists and folds of the organ and its membranes, so that necrosis is a matter of conjecture in any particular case. In the aged, however, the appendicular vessels themselves are so thickened as to be unable to dilate and relieve the congestion even if otherwise unobstructed, so that gangrene rapidly supervenes in almost all cases. That this is so is shown by the descriptions of the appendix in the 110 cases investigated. The 26 cases seen on the first day of the disease were "engorged"; all but 2 of the 23 second-day cases were gangrenous, 6 with perforation; while the 18 third-day cases were all gangrenous and 13 were perforated. Further, of the 31 cases which recovered without appendicectomy, 27 have been "followed up," and only 2 have had recurrent symptoms, so that in the great majority of these cases the presumption is that the appendix sloughed during the acute attack. Five indeed had subsequent operations, usually for ventral hernia, and the appendix was found to have completely disappeared in each case, except one in which it was reduced to a partially fibrosed organ one inch long.

In the acute attack peritonitis develops as the appendix progresses towards necrosis. Thus in the cases described above, those seen on the first day had a little clear fluid only; by the second day the fluid was purulent, being shut off by adhesions in half the cases, but diffusing over the lower abdomen in the others. On the third day there was diffuse peritonitis in two-thirds of the cases, and abscess-formation in one-third, while all the patients who lived to the fourth day and after had an abscess. The almost constant course of acute appendicitis in old people is therefore—first day, engorgement; second day, gangrene and local peritonitis; third day, perforation with general peritonitis or abscess-formation; fourth day and after, abscess.

TREATMENT AND COMPLICATIONS

The problem of the elderly patient with acute appendicitis therefore is very different from that of the young one. In the latter case the actual condition of the appendix is unknown, but immediate operation is necessary to forestall the possible onset of gangrene; the operative risk is small and appendicectomy is indicated to avoid recurrence of trouble that might occur in a damaged but surviving organ. In the elderly patient, on the other hand, while the

condition of the appendix is not in doubt, the certainty of necrosis precludes the possibility of recurrent trouble; the operative risk, however, is considerable and becomes the deciding factor in treatment.

There are two great dangers to be considered: general peritonitis which is the result of the disease, and pneumonia which is the result of the treatment. It need hardly be said that the necrosis of the appendix does not in itself constitute a danger to life, except in so far as it may cause spreading peritonitis. If the process is already localised in a palpable abscess, non-operative treatment is indisputably the best; 15 such cases in this series were treated in this way with only 2 deaths from pulmonary embolism, a complication which could hardly have been avoided by operation. But in the more acute cases with no abscess, seen on or before the third day, the foregoing analysis shows that there is an even chance of the development of diffuse peritonitis, which when once generalised, is invariably fatal. Operation must therefore be undertaken to prevent the spread of purulent fluid over the peritoneal cavity, but for this purpose it is *not necessary* to remove the appendix. A drainage-tube placed accurately alongside it will prevent the pressure of fluid exudate which alone causes its diffusion. Adhesions will be able to form, and both the fluid and the necrotic substance of the appendix itself will be discharged on to the dressings.

At first sight the difference between this procedure and actual removal of the appendix may seem to be slight, but it must be remembered that with an old patient an operation *definitely planned not to remove the appendix* is a very different matter from one designed to remove it if possible. In the former case only a small incision is necessary over the iliac fossa, big enough to admit first the exploring finger and then the drainage-tube, and no disturbance of intestines is occasioned. Moreover, the muscular relaxation of the abdominal wall need not be complete, so that modifications in anaesthesia can be employed with great benefit to the patient. On the other hand, removal of the appendix necessitates complete muscular relaxation and general or spinal anaesthesia is necessary, with the attendant risk of chest complications. The wound must also be of adequate size, and all protective adhesions are inevitably destroyed as the caecum and appendix are delivered to the surface. Not only therefore is the immediate operative strain on a frail subject greater with the anaesthetic and manipulations involved in removing the appendix, but the final result is prejudiced by the added risks of spread of peritonitis at the time of operation, and of pneumonia following the longer and deeper anaesthesia required. Particularly is this the case when operation is performed on the critical second and third days when early adhesions are beginning to form. Of the fatal cases 70 per cent. were operated on at this stage and the post-mortem records show many in which peritonitis, actually seen to be localised at operation, has become general after the disturbance involved in appendicectomy. Old people seem to be able to make one effort to limit the peritonitis by adhesions, but if these are broken down the pus will spread, even though the source of infection is removed.

RESULTS OF VARIOUS PROCEDURES

These points are well illustrated by the results of the various methods of treatment (by many different surgeons) in the 110 cases investigated. There were

in all 22 deaths (20 per cent.) and autopsies were performed in 15 cases. Discounting 2 cases not operated upon, and 4 cases that were moribund on admission to the hospital, there were 16 deaths, all of which followed removal of the appendix. Of these 9 were "ill" patients with purulent fluid in the pelvis, but 7 were described as "not ill," having only a slight rise of temperature and pulse and no spreading peritonitis. Eight deaths were due to general peritonitis with paralytic ileus. In none of these was the fluid generalised at the time of operation, while in 4 of them the note made at operation stated that the fluid was definitely shut off by adhesions. It is fair to assume that certainly 4 and probably more of these cases might have been saved by the more conservative operation. There were 4 deaths from broncho-pneumonia—2 after spinal and 2 after ether anaesthesia—and there can be no doubt that the anaesthetic was at least a contributory factor in the onset of this fatal complication. The remaining deaths were due to pulmonary embolus, septicaemia, mechanical intestinal obstruction, and persistent intestinal fistula—the 3 latter following a prolonged and difficult appendicectomy in each case. The 16 deaths after appendicectomy were due therefore not to any fault in technique at operation, but at least in part to the type of operation performed.

Of the 88 cases that survived, 13 were appendix abscesses that recovered without operation. In 57 cases the patients were described as "not ill"; but 18 were "ill," 13 of whom were saved by simple drainage, while 5 had the appendix removed. The statistics can best be appreciated from the practical standpoint of the original condition of the patient, whether he was "ill" or "not ill," clinical terms based on the aspect of the patient, pulse-rate, and general toxicity. Of 64 patients described as "not ill" the appendix was removed in 59 cases with 7 deaths—an unnecessarily high mortality of 12 per cent.—while simple drainage was performed in 5 cases without a death. But of the 31 "ill" patients the mortality after appendicectomy was 64 per cent. (14 cases with 9 deaths), while after simple drainage it was only 24 per cent. (17 cases with 4 deaths), although these latter were the most advanced cases of the series, including the four described above as moribund on admission.

The possibility of intestinal fistula formation has been considered. There were 2 instances of this complication (one of them fatal) both of which were due to sloughing of the caecal wall after a difficult operation for removal of the appendix. In no case was simple drainage followed by a persistent fistula.

The case-records bring out another point—the greatly increased death-rate in those who had a paramedian incision. Of the cases operated on by this route 40 per cent. died, as against 10 per cent. after a right iliac incision. Descriptions of the autopsies after paramedian incision in these old people show a large proportion of grossly infected wounds, with extensive suppuration of the abdominal wall, and 3 cases of secondary rupture of the wound. Moreover, it is in the cases with a paramedian incision that the fatal spread of pus which was localised at operation is most striking. Allowance must of course be made for those cases where the diagnosis was in doubt, and the paramedian incision was made for exploratory purposes, but even so the best chance of survival for the patient is provided by drainage of the appendix area through a stab wound over it, with the minimum of peritoneal disturbance. In point of fact, however, the diagnosis was rarely in doubt in these cases, the great majority of which

gave the classical sequence of generalised abdominal pain, vomiting, and tenderness in the iliac fossa. A muscle-splitting incision over the appendix big enough to admit the diagnostic finger and the therapeutic tube cannot subsequently rupture and its infection is of no consequence. It is a further advantage after this incision in an old, apathetic patient, to be able to get him up on a couch to stimulate his waning interest in life, without risk of bursting the wound.

With regard to the anaesthetic, in this series of cases it has been almost exclusively either ether or a spinal novocaine preparation. The incidence of pulmonary complications was about the same with each method. However, in these cases, appendicectomy, if possible, was the object of the operation, and complete relaxation of the abdominal wall has been demanded of the anaesthetist. But if operation be undertaken with the specific purpose of drainage only, relaxation need not be complete. Gas-oxygen anaesthesia after omnopon-scopolamine premedication can be used and by the judicious use of carbon dioxide the anaesthetist can control the ventilation of the lungs. By this method congestion of the lungs is diminished rather than increased, and the bronchi are not inflamed by irritant vapours, so that the likelihood of post-operative chest complications is reduced to the minimum.

CONCLUSION

In conclusion, it may be repeated that, on account of the stereotyped progress towards necrosis in three days of the acute appendix in old people, the treatment becomes simplified. While there is nothing to be gained by removing an appendix that will remove itself, the conservative operation of simple drainage is attended by a much lower mortality, complications are fewer, fistula does not develop, convalescence is easier, and the patients do not get subsequent trouble.

I should like to acknowledge my indebtedness to the authorities at the London Hospital for their kindness in allowing me to publish particulars of their case records, and to Sir James Walton for his advice and criticism.

SURGERY IN THE TREATMENT OF PRIMARY SKIN CARCINOMA

By H. T. SIMMONS, Ch.M. Manch., F.R.C.S. Eng.

ASSISTANT SURGEON TO THE CHRISTIE HOSPITAL AND HOLT RADIUM INSTITUTE, MANCHESTER

IN the vicinity of the radium centres the treatment of the various types of primary carcinoma of the skin is being undertaken mainly by the radium officers and constitutes their most successful class of case; but elsewhere in the country surgery still remains the only practical treatment available. Quite a number of the patients that have been submitted to surgical treatment are referred eventually to a radium centre in the hope that radium may remove the recurrent nodules of growth that have appeared in the operation scar, and, as second attempts at the treatment of malignant disease are notoriously poor and admittedly so, it has seemed worth while to examine these cases in some detail in order to discover, if at all possible, the fault in the original operation.

During 1934 there were referred to the Christie Hospital and Holt Radium Institute 5 cases of

primary epithelioma of the skin and 12 cases of rodent ulcer that had been treated surgically elsewhere and were showing recurrence in the area of the operation. Occasionally the diagnosis of malignancy has been missed, a microscopical section has not been examined, and the follow-up of the patient omitted. This is sufficiently common to warrant the dogmatic statement that every hyperplasia or indolent ulceration of the skin that comes to operation should be excised as though it were malignant, have the complete lesion examined by a pathologist, and be carefully examined at monthly intervals for at least a year, attention being directed particularly to the operation scar and the regional lymphatic glands.

When there is recurrence we find that almost always the operation scar is linear and the nodules

are situated about the middle, never near either end. Usually a few months have elapsed since the operation and the regional lymphatic glands show some enlargement, unless the carcinoma is arising in fibrosed tissues such as an old burn or lupus scar.

It is very definitely true that metastatic involvement of lymphatic glands is commoner and earlier in these cases with ineffectual treatment of the primary lesion than in those in which a cure has been obtained. As yet the treatment of the lymphatic glands lies in the province of the surgeon, but why is radiotherapy displacing surgery in the treatment of the primary lesion when it is well recognised that surgical excision offers a speedy and certain cure, excepting those cases in which anatomical consideration, or the general condition of the patient demands radiotherapy?

The answer seems to be that radiotherapy is observing the principles taught by the surgery of malignant disease, whereas the surgeon, haunted by the question of repair, cuts down the margin of safety and pays the inevitable price. Mr. A. H. Burgess used to teach that one surgeon should remove the cancerous breast and another deal with the closure of the wound, so that the skin removal should be adequate and the judgment of the extent of its removal not affected by the problem of repair. The lack of application of these principles and teaching is shown by the nodules recurring in the centre of the scar, suggesting that the usual elliptical incision has failed and should be condemned.

Given a lesion one centimetre in diameter an effective dose of gamma radiation would be applied over a circular area three centimetres in diameter; or, in other words, with a lesion the size of sixpence the area effectively treated would be the size of a five-shilling piece. Every surgeon teaches that a

malignant nodule should be excised with a margin of healthy skin of at least one centimetre in width and this means that if the lesion is the size of a sixpence the area marked out for excision must be the size of a five-shilling piece, the marginal difference of the two coins being only one centimetre. Is this what is actually done in practice? As regards depth, again one centimetre from the deepest part of the lesion is the rule and particularly here must care be taken, erring on the side of taking too much and including the deep fascia if that comes anywhere near these limits. Some of the recurrences undoubtedly come from the depths of the lesion, and here surgery should be able to improve on radiotherapy, especially the mould application of radium. Repair of the raw area is a secondary consideration and is best attempted by excising triangles of skin at opposite

FIG. 1.—Epitheliomatous ulcer arising in old burn scar. Three previous operations.

FIG. 2.—A year after excision and immediate Thiersch graft.

ends of a diameter of the area which lies along the natural line of stress in the skin, and then a little under-cutting will allow approximation of the edges of this secondarily elliptical skin incision. Failing this, primary or secondary Thiersch grafts give excellent results, depending on the depth of the wound, and if the deep surface be hard so that, as on the skull, firm pressure can be obtained, an immediate Wolff graft takes perfectly.

Diathermy is proving a pitfall in that, although the area necrosed is larger than appears at operation, this fact is tending to excuse, in the mind of the operator, a non-radical procedure with necessarily poor results: and, unless frankly palliative, the area treated should be as extensive as surgery dictates, the little extra obtained being credited to the diathermy and not made to appear on the debit side. Watching the after-results of extensive diathermies I have been agreeably surprised at the rapid and extensive repair of the lost tissues, but the process slows very rapidly towards the centre, so that for a long time the patient has a raw area in the middle of his diathermy scar. This area slowly heals, but in a considerable number of cases there has been a sudden and inexplicable growth of squamous carcinoma, commencing at the edge of the ingrowing epithelium, in cases that the operator felt sure he was well beyond the limits of malignant disease. Particularly has this been noticeable in diathermies in tissues already scarred and it is sufficiently striking to suggest that squamous epithelium growing over a large cicatricial area tends to become anaplastic the further it grows from the normal skin and normal blood-supply. Accordingly, we have resorted to wide surgical excision with immediate Thiersch grafting and the results are more encouraging, especially as careful preparation of the carcinoma with eusol

dressings renders the field of operation sufficiently aseptic to ensure a large percentage of successes with the grafting.

The accompanying photograph (Fig. 1) is taken from a case of squamous epithelioma, arising on the scar of a burn received 24 years previously. During 1933-34 the patient had two surgical removals and one diathermy of the ulcer at other hospitals. In July, 1934, I excised the ulcer, applying an immediate Thiersch graft. Fig. 2 shows the condition a year later, with no evidence of recurrence.

CONCLUSION

From this review it appears that a primary elliptical excision of a skin carcinoma tends to encourage the surgeon to trespass on the margin of safety and that better treatment is obtained if the tumour is first excised according to recognised surgical principles in the treatment of malignant disease, and the repair is regarded as a second and distinct problem of plastic surgery.

Clinical and Laboratory Notes

UNDULANT FEVER TREATED BY PROTEIN SHOCK

By G. E. BEAUMONT, D.M. Oxon., F.R.C.P. Lond.
PHYSICIAN TO THE ROYAL MASONIC HOSPITAL, LONDON; AND
A. P. M. PAGE, M.D., M.R.C.P. Lond.
RESIDENT MEDICAL OFFICER AT THE HOSPITAL

Manson-Bahr¹ recorded in 1933 a case of undulant fever successfully treated by the intravenous injection of T.A.B. (typhoid and paratyphoid organisms) "as a means of inducing others to try out this method of treatment." Encouraged by his article we applied the method to a case recently under our care, with equally successful results.

The patient, a male aged 50, who had not been abroad, had suffered for the last eight years from periodical attacks of "ague," occurring two or three times a year. He had been accustomed to drink one and a half pints of milk a day for several years, warmed but not boiled. Up to three years ago the milk was, the patient understands, pasteurised, but for the last three years it was not pasteurised. Six weeks before admission he had ague attacks culminating in an acute illness, described as "acute influenza," characterised by prolonged pyrexia with severe headaches and almost daily rigors. The temperature rose on occasions to 105° F., and was usually between 99° F. and 102° F. It was suggested that he was suffering from a streptococcal infection.

The patient was admitted to the Royal Masonic Hospital on April 17th, 1935, and the same evening the temperature rose to 103° F., with pulse-rate 140 and respirations 24. The temperature gradually subsided to normal during the next five days, but rose again to 100.4° on April 26th and to 102.4° the following day with another rigor. During the rigor there was a feeling of coldness, chattering of the teeth, shivering, shaking of the limbs, followed by flushing of the face, throbbing in the head, lachrymation, and sweating. No enlargement of the liver, spleen, or lymphatic glands was detected. A blood count at the height of the rigor gave the following result: red cells, 4,290,000; hemoglobin, 80 per cent.; colour-index, 0.9; white cells, 11,000; polymorphonuclears, 56.7 per cent.; eosinophils, 1.3 per cent.; small mononuclears, 37.3 per cent.; large mononuclears, 4.7 per cent. No malaria parasites were found. The urine showed no

abnormality and was sterile. The serum agglutinated *Brucella abortus* in a dilution of 1 in 3000 (375 standard agglutinin units).

The patient had also suffered from a rash for the last ten years, which was diagnosed by Dr. A. C. Roxburgh as the adult type of urticaria pigmentosa.

The temperature did not fall to normal until six days after the second rigor. On May 4th, having previously ascertained that the blood pressure and electrocardiogram were within normal limits, an intravenous injection of 100 millions T.A.B. vaccine was given. Within an hour a severe rigor occurred, the patient was much collapsed and cyanosed and appeared very ill. The temperature rose to 104° F. and the pulse-rate to 112. A subcutaneous injection of 1 c.cm. Cardiazol-ephedrine was given, and repeated twice at six-hourly intervals. The condition of the patient had considerably improved an hour after the rigor, which he said was more severe than those he had previously experienced. He vomited two or three times and complained of abdominal pains which persisted for a few days. The subsequent course was uneventful. The temperature fell to normal in four days and did not rise again. The serum was examined 19 days after the T.A.B. injection and the agglutination titre was now only 1 in 50 (6 standard agglutinin units). The patient left the hospital on May 25th and 17 weeks later reported that he was quite well, had returned to work, and was also playing tennis.

Although in this case the protein shock therapy had a beneficial result, the severity of the reaction might render it dangerous in the presence of cardiovascular degeneration.

Our thanks are due to Dr. G. L. Eastes for carrying out the pathological investigations.

BILATERAL DOUBLE URETER

By ALEXANDER LYALL, M.B. Glasg.
ASSISTANT PATHOLOGIST, ROYAL INFIRMARY, GLASGOW

DOUBLE ureter is one of the commoner anomalies met in the kidney and is readily understood if one considers the development of the organ. The anlage of the ureter appears as a bud from the lower end of the Wolffian duct. It has an inherent tendency to divide, which it does normally when it reaches the kidney rudiment, forming first the major, and when these themselves divide, the minor calyces. Division may however take place prematurely, and we have various degrees of double ureter varying from both opening into the bladder by a common inlet to their union a little below the pelvis of the kidney. Division of the anlage may take place actually before the bud has formed, resulting in two ureters opening into the bladder separately. Cases of unilateral duplication of the ureter are well known; but cases of bilateral double ureter are rare and worthy of record. The following is such a case.

Mrs. A., aged 70, was admitted to hospital complaining of a blood-stained vaginal discharge which had lasted three months. Adenocarcinoma was revealed by curettage and complete hysterectomy and bilateral salpingo-oophorectomy was performed. Ten days after operation she developed acute cystitis, and this persisted for three weeks despite treatment. She then developed abdominal distension, became gradually weaker, and died.

Post mortem diffuse peritonitis was found, with areas of acute ulceration in the colon and lower rectum and an acute cystitis. In addition, there was a double ureter to each kidney, opening from their upper and lower parts (see Figure). On the right side the ureters opened separately into the bladder, the openings lying beside each other at the right end of the interureteric bar. On the

¹ Manson-Bahr, P.: THE LANCET, 1933, i., 1179.

left side the lower ureter opened into the bladder through an orifice at the normal site of the ureteric opening. The upper ureter opened into the urethra at its exit from the bladder and appeared to run through the fibres of the sphincter urethrae.

Drawing (semi-diagrammatic) to show the origins of the double ureters and their point of entry to the bladder.

This tube showed much dilatation, measuring 2 cm. in diameter at one part. It also showed evidence of inflammation of long standing, with fibrous thickening of its wall and periureteritis. The related upper half of the kidney was replaced by a thick sac containing a quantity of pus. Attached to the lower part of the sac were the remains of the left kidney which appeared quite normal and very well demarcated from the infected upper half. The ureter ran from it in a normal manner and crossed in front of the infected ureter a little above the pelvic brim.

The interesting features in this case are: (a) The bilateral double ureters which opened symmetrically into the bladder, the upper one on the left side opening into the urethra. This ureter could empty itself only when the sphincter urethrae was relaxed—i.e., during actual micturition. Hence it had become greatly distended and later infected, the kidney being ultimately replaced by a bag of pus lined by granulation tissue. (b) The sharp fibrous tissue demarcation between the upper and lower halves of the kidneys on either side is interesting. This was noted also by Legueu and Luque,¹ who concluded that these subjects should be considered as having four distinct kidneys although those on each side were welded together forming an apparently single kidney. Legueu demonstrated that their vessels were distinct. Luque, who diagnosed the condition during life by urography, showed that the fluid eliminated by each of the four ureters was quite different in quality and in chloride and urea content. This is interesting, for it means that if a diseased condition of the kidney tissue excreting into one of the four ureters be found clinically, the treatment need not be complete nephrectomy on that side but rather a heminephrectomy with excision only of the diseased half, leaving the blood-supply of the remaining half. It is noteworthy that the ureter which opens lowest in the bladder comes usually from the higher of the two halves of the kidney. (c) The patient lived to the age of 70, apparently without symptoms, although infection of the affected ureter and kidney had obviously been present for a long time.

My thanks are due to Prof. James Hendry for the clinical notes of this case and to Prof. J. Shaw Dunn for his help.

¹ Luque, T. M.; Urol. and Catan. Rev., 1932.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF OBSTETRICS AND GYNÆCOLOGY

At the meeting of this section held on Oct. 18th, with Dr. W. FLETCHER SHAW, the president, in the chair, the subject of discussion was the treatment of

Breech Presentations

with special reference to cases of extended legs and arms.

Dr. J. W. BURNS (Liverpool) opened the discussion by considering the complete or fully flexed breech. In most breech cases seen in hospital, he said, it was impossible to demonstrate the presence of any one of the aetiological factors given in works on obstetrics. He doubted whether the incidence of contracted pelvis was much greater in cases with this form of presentation than in vertex presentations; at least contracted pelvis—except in its more gross form—could not be regarded as a cause of breech presentation at 36 weeks. Certain abnormalities—for example, placenta previa and such conditions as hydrocephaly and anencephaly—should be eliminated before proceeding to version, since some of these abnormal conditions were more readily dealt with if the presentation remained a breech. Prophylactic external version carried considerable risk of separation of the placenta, and the danger was increased under anaesthesia, when too forcible manipulations were liable to be used; sometimes stillbirths resulted from this operation. Version should be performed not later

than the thirty-sixth week, if that could be managed and preferably without an anaesthetic; failure suggested extended legs, and in these cases failure was liable to occur even under anaesthesia. In the management of the first stage, in addition to the usual measures, Dr. Burns advocated the use of an abdominal belt as soon as labour commenced; a very efficient adjustable pattern devised by Sister Miller was used at the Liverpool Maternity Hospital. The uterus and abdomen should not be handled throughout the second stage for fear of encouraging separation of the placenta. It was not known at what stage of delivery the placenta ceased to function, but he believed the placental body left the uterine wall much sooner than was usually thought; in breech cases it ceased to supply oxygen to the infant from the moment the head was passing through the pelvic brim. As soon as the perineum was distended by the descent of the buttocks, the patient was placed in the cross-bed posture, with her legs in the lithotomy position, Clover's crutch being very useful. When the buttocks and feet were distending the vulva, the feet were secured and lifted over the perineum. When the umbilicus was born, a loop of the cord was pulled down and then left. Usually the scapulae were born spontaneously, or with the assistance of some traction on the trunk; if the flexed arms did not follow immediately, they could be hooked out with the fingers. Describing his method of delivering the head, Dr. Burns said he had the mother's buttocks well over the edge of the bed, and as soon as shoulders and arms were born, the child was allowed to hang from the vulva; the weight of its body acting through

the neck brought the suboccipital area of the skull in contact with the back of the symphysis if the head was above the brim, or the descending rami of the pubes if the head was in the pelvic cavity. The head was thus caused to rotate on its horizontal axis, so bringing the suboccipito-frontal diameter through the brim. The body-weight maintained the head in the position of flexion while in the pelvic cavity, and this flexion was maintained during delivery. The attendant should stand sideways to the patient's vulva, using only one hand to grip the legs; the traction should keep the child's neck taut, so preventing the occiput from receding into the pelvis. This traction was maintained and the child lifted upwards and outwards through 180°. If delay occurred, suprapubic pressure exerted by the operator's left hand to the head would bring about delivery. This method helped to eliminate undue haste, as the operator must wait until the suboccipital area of the foetal skull could be seen in the subpubic angle before delivery was attempted.

Dr. C. McINTOSH MARSHALL, after a short historical survey of the methods for delivering the buttocks, submitted some conclusions reached from the delivery of over 40 cases of primigravidae in which the legs of the foetus were extended along its abdomen. No infant under 5 lb. in weight was included in the series spoken of; in a number unsuccessful attempts at external version had been made. In only one case was labour induced, and in that the patient had gone beyond the expected date. The cases were studied especially in regard to (1) dilatation of the cervix, and (2) the descent of the buttocks. In emergency cases one careful examination was made for the purpose of determining the degree of roominess of the pelvis. Three important observations had emerged: (1) in 40 out of 42 cases, as a result of the use of the natural powers alone, the buttocks arrived completely on the perineum before either mother or her foetus showed any sign of distress; in some this occurred just as assistance was about to be offered. (2) In no case did the mother show signs of distress. (3) In no case was there distress when the foetus was issuing from the vulva. It was the perineum which offered the greatest resistance to the buttocks. Dr. Marshall declared that while early prophylactic bringing down of the legs might be an excellent method of treating these cases, it was unnecessary. Forty of the 42 cases were delivered with the legs in the fully extended position; all were alive at the moment of the birth of the buttocks. One infant was stillborn, the cause of the death remaining unexplained. Another died from laceration of meningeal septa; there was great difficulty in delivering the head through a contracted pelvis. The foetal mortality was 4.76 per cent. Dr. Marshall then exhibited a cinematograph film showing the delivery of four infants in the Liverpool Maternity Hospital.

Dr. DONALD ROY said his contribution described a routine evolved by the ward sisters and the ordinary hospital residents at the York Road Lying-in Hospital. During pregnancy external version was attempted at varying dates between the thirty-first and thirty-eighth weeks in all cases of breech presentation in primigravidae, and in many multiparæ too. Taking as a sample year 1930, external version was attempted in 59 cases—i.e., 29 primigravidae, 30 multiparæ—and in all but 3 (primigravidae) it was successful. If version failed, even under general anaesthesia, the cases were left either to go into labour at term as breech cases, or in some cases labour was induced, either prematurely, at 36 to 38 weeks, or at term.

In ten years 155 cases with breech complications were recorded, excluding very small premature infants, twin presentations, macerated children, foetal deformities, antepartum hæmorrhage, and version performed because of difficulties of labour. When labour occurred, the legs (which, in 63 per cent. of primigravidae and 41 per cent. of multiparæ were extended) were nearly always left to be born naturally, or, at most, flexed at the vulva when born to the knees. Seldom was any difficulty or delay experienced. The average duration of the second stage in these 155 cases was 1 hr. 54 mins. in primigravidae, and 48½ mins. in multiparæ. In 3 of the former and 1 of the latter groin traction was used, and in 2 the legs were brought down. Dr. Roy and his colleagues considered, as the result of experience, that the risk of trouble from extension of the legs when antenatal work was properly done had been grossly exaggerated. The important factor was the size of the child in relation to the size of the pelvis. Cases of impaction of breech could be avoided by early version or by the induction of premature labour. Both arms were extended in 53 per cent. of the primigravidae, and one arm in 9 per cent.; both arms were extended in 47 per cent. of the multiparæ, and one arm in 3 per cent. of them. In 43 out of 48 cases in primigravidae with extension of one or both arms, one or both had to be brought down. Extension of the arms was present and was the chief cause of difficulty in all the 11 cases of stillbirth from difficult labour. Dr. Roy considered that extension of the arms was the most important and dangerous complication of breech delivery, because of its frequency and the large proportion of cases in which help was needed. Delivery of the head was hastened by jaw and shoulder traction in 15 primigravidae and in 6 multiparæ, and by means of forceps in 1 primigravida. Summarising his results, he said that among 77 primigravidae there were 7 stillbirths and 1 neonatal death, a foetal mortality of 10.3 per cent. In 78 multiparæ there were 7 stillbirths, a foetal mortality of 8.9 per cent. There were no maternal deaths, and no cases of Caesarean section for breech presentation.

Mr. ALECK BOURNE said he had always felt that in a large number of the cases it was better to bring the legs down. Cases of impacted breech occurred due to extended legs, resulting in obstructed labour; there might also be extended arms. In a group of primigravidae with soft parts not easily dilated and with large babies, the legs would not come down when the os was fully dilated. By bringing them down early opportunity was given to bring the arms down by putting the hand a little higher. Sometimes he had slipped a loop of tape over the wrists to keep the arms down. If arms and legs were brought down at the same time, one of the chief causes of breech mortality was avoided. He seldom experienced trouble with delivery of the head. Rather than risk an impaction with obstruction he would bring legs down even when apparently unnecessary.

Mr. EARDLEY HOLLAND said he had been surprised to find that, as a result of a large number of post-mortem examinations on foetuses born dead as a consequence of breech labour, there was evidence of excessive cranial compression in 88 per cent., with tears of the tentorium and intracranial hæmorrhage. The teaching in his student days was that after the body of the foetus had been born it was imperative that the head should be delivered quickly, as otherwise the foetus would die of asphyxia following upon cord compression. Investigation had shown how erroneous was that teaching. When morphia and

scopolamine were used to relieve the pain of labour, it was found that the foetus could remain for as long as 20 minutes in a state of complete apnoea, and then breathe naturally. He had accordingly urged slow delivery of the head, and also perineotomy; insisting that the main problem was delivery of the foetal head in such a way as to obviate its compression. He did not think that external version was dangerous in the hands of the educated obstetrician. Provided the breech had not sunk into the pelvis, the first thing to do was to compress the foetus between head and breech, rolling it up like a hedgehog. He was against bringing down the legs as a regular practice; unless the foetus was very large, that was not usually necessary in multiparæ. If, after the breech had come down on to the pelvic floor, there was a delay of half an hour, he made it a rule to bring down the leg so as to steer clear of an impacted breech.

Mr. G. F. GIBBERD confessed to depression about the results in breech cases. Some said that in these cases the great difficulty was due to the arms, others feared the danger to the head. His view was that even if there was difficulty in delivering the arms while the head was easily delivered, there were three chances to one that at the autopsy intracranial hæmorrhage would be found. To lower the present mortality from this cause he could only suggest external version, which was not a dangerous procedure. In his own hospital, in 204 external versions the stillbirth-rate was 2 per cent. An occasional cause of death in the foetus was atelectasis; when the foetus was born, its head should be held lower than its feet; otherwise if fluid was present in the trachea it would enter the alveoli.

Dr. G. W. THEOBALD said that every obstetrician should have a constant technique. When once the breech came down to the outlet and the cervix was fully dilated, the patient should be anaesthetised and delivery carried out. He contended that it was wrong to bring down the anterior arm first; the posterior arm should receive first attention. If the operator placed one hand in the vagina, kept the head flexed, and pushed the head through from above, intracranial hæmorrhage would be avoided. That meant that the patient must be thoroughly anaesthetised; a half-anaesthetised woman was more difficult to deliver than one fully conscious. When the breech had been delivered it was important to squeeze the chest and to keep it constricted until the air-passages were cleared.

Dr. W. H. F. OXLEY said that in his long experience of general practice he had had a large number of breech deliveries. Many were impacted with extended legs, which had been left too long. His cases were looked after by midwives, not by doctors. In all primiparæ he brought the legs down; if this were not done as a regular procedure, one would not be able to bring down the legs in difficult cases without tearing the vagina. He always arranged to be called when the os was fully dilated. The legs having been brought down, the midwife located the child's head and pushed it down without traction. He did not pull on the trunk of the foetus. He had delivered over a thousand cases with extended legs in ten years, with good results.

Mr. A. J. WRIGLEY agreed that breech presentations should be regarded as a warning of other possible complications. At St. Thomas's the breech figures had definitely improved since the York Road technique, described by Dr. Roy, was introduced. Recently Dr. Marshall's methods had been adopted there, since when there had been no case of stillbirth nor of neonatal death.

Mr. J. D. S. FLEW spoke in favour of early version. In 600 cases of external version, of which 200 were between the thirtieth and thirty-fourth weeks, there was no instance of labour arising from the version.

Miss J. M. MOORE said that in 1934, at the Royal Free Hospital, breech cases in primigravidae numbered 26; only 4 responded to external version between the thirty-sixth and thirty-ninth weeks, and they were subsequently delivered as vertex cases. That was a poor result for version. In some the condition was not diagnosed until the patient went into labour, and in some others version was contra-indicated because of engagement of the breech, or because of toxæmia, and there was one case of primary thyrotoxicosis. Epiphysiotomy was done in 23 out of 30 cases. The stillbirth-rate was 2 per cent.; the gross mortality of neonatal and stillbirth cases was 16.6 per cent.

Prof. SCHILLER (Vienna) said that in his clinic much more attention was being paid to the condition of the foetal head than to that of asphyxia. A colleague of his had shown that asphyxia played no important part in causing death in the foetus. In 90 per cent. of the cases investigated, hæmorrhage in the tentorium could be proved, while the deaths from asphyxia did not number more than 2 to 3 per cent. In his institution pituitary extract was very frequently used; it was regarded as "pharmacological forceps." If any traction was considered necessary, it was exerted on the neck, not on the feet, and even this was not done until after the use of pituitary extract.

The PRESIDENT was surprised that no speaker had mentioned the practice of ironing out the vagina in order to ensure plenty of room there, a procedure stressed by Potter of Buffalo, who had one of the largest obstetric practices in the world.

Dr. BURNS, in reply, said he believed many babies were killed at the vulval orifice by injury to the base of the brain. In selecting the legs for traction he was anxious about the neck vertebrae; in his cases there was no evidence of injury to these. It was important in these matters to legislate for students and beginners, not for experts.

SECTION OF COMPARATIVE PATHOLOGY

A MEETING of this section was held on Oct. 23rd, when Prof. J. C. G. LEDINGHAM, F.R.S., gave his presidential address on the

Comparative Study of Clinically Allied Viruses: Some Unsolved Problems of Edward Jenner

He said that he proposed to consider the poek diseases with particular reference to the problems they present to the student of comparative pathology and fundamental virus research. Since Jenner made protection against small-pox possible great theoretical advances had been made, and we could now with fair certainty speak of and manipulate the actual virus agent; but the only advance which we could register in Jenner's sphere, an advance as yet only tentatively exploited, was the rendering of Jenner's prophylactic more æsthetic and acceptable by administration of the virus of vaccinia in its purest form freed entirely from associated organisms.

The origin of the practice of variolation was lost in antiquity but certainly went back a thousand years or more before the Christian era. Its discovery was doubtless the culmination of frequently and independently observed phenomena suggesting that small-pox was not likely to be contracted twice and

that infection entering the body through skin traumata ran a more benign course than that following natural infection. Small-pox came to Europe probably round about the sixteenth century and though variolation was held by some to have been independently discovered and secretly practised by peasants in various western countries, it was its importation from the east, largely through the efforts of Lady Mary Wortley Montagu, that brought the method into prominence in the eighteenth century. Fatal issues in the hands of capable inoculators were surprisingly small, possibly because the eastern ritual was adopted—insistence on spare diet, cooling drinks, and life in the open—for those inoculated. The recognised necessity of paying careful attention to the state of health of candidates for vaccination in modern times was indeed only a reflexion of an old-established eastern rule. The question whether any genuine lasting attenuation of the variola virus was achieved by the practice of variolation in human passage was of great interest. There seemed little doubt that certain inoculators who carefully selected their material only from primary vesicles obtained results approaching closely to those following vaccination. Secondary pocks might be either very few or absent. Were such human-passaged strains of variola available now, it would be of the greatest interest to determine how far, if at all, they might differ antigenically from the variola-vaccine derived by passage from man to other mammalian species. The problem was, in fact, whether the change from variola to the attenuated variant known as vaccinia could take place without transference to another host. Prof. Ledingham concluded his remarks on variolation by pointing out that it was an effective method of small-pox prevention, not without risk to the individual and the community, which was essentially a product of the deductive logic of independently reasoning beings in probably many isolated communities. In this country it had a long life and survived, though precariously, into Jennerian times. For all time it would occupy an outstanding place in the development of immunology as a way of forestalling a natural disease and robbing it of much of its power for harm.

The advent of Jenner and vaccination opened up an entirely new field of endeavour in which for the first time observation and experiment went hand in hand. Prof. Ledingham quoted effectively in the laboratory language of to-day the two cardinal experiments recorded in the famous *Enquiry* of 1798 on which rested Jenner's claim to immortal fame, and proceeded to discuss the nature of cow-pox—which was still abroad in the world—and what virtue it had that made it, as Jenner had experimentally demonstrated, an apparently effective prophylactic against human small-pox. This was a region of old and perhaps still smouldering controversy which could now be approached calmly, owing to the rise and gigantic development of the bacteriological era, with, of late, more than an inroad into the nature of those agents called viruses of which Jenner was the pioneer student. Jenner himself approached the problem by a study of the origin of cow-pox which he linked with a disease of horses known as the grease. Three clinical entities, the grease in the horse, the cow-pox of the cow, and the casual cow-pox in man, were, he found reason to believe, etiologically connected and strictly in this order of passage, infected matter being conveyed on the hands of farm attendants from the lesions on the horse's heels to the teats of cows, and thence to other milkers. Jenner had to abandon his idea

of the equine origin of cow-pox, but it was now quite clear how this idea arose. John Loy in 1801 showed that there were two kinds of grease, only one kind being communicable to man and cow. The grease that was communicable came from horses in which the local inflammatory condition of the heel was only part of a more general exanthem, while the non-infective grease might be any sort of banal inflammatory condition in the region of the heel. In recent years the grease had been shown definitely to be one of the local manifestations of horse-pox or contagious pustular stomatitis, and as horse-pox it took its place with cow-pox in a common problem still unsolved. Were these diseases *sui generis* or were they, wherever they might be found, due invariably to unwitting variolation or vaccination of the horse or cow by the hand of man? Current text-book opinion postulated for these diseases a purely extraneous origin—i.e., they were held always to be man-induced, but Prof. Ledingham had never been satisfied with the evidence supporting this view. He pointed out that the direct variolation of the cow was not easy; it had long been attempted without success, though eventually by direct or indirect means and artifices such as the use of intermediary animals like the monkey and rabbit it was achieved, a new source of vaccine lymph became available and recourse to casual cow-pox was rendered unnecessary. Prof. Ledingham spoke briefly of the efforts made by himself and his colleagues at various times in recent years to secure a vaccinia-like variant from variola of the alastrim type in this country, by rabbit passage alone or monkey passage followed by rabbit passage, and of the light shed by these efforts on adaptation problems. Doubtless the question of virus adaptation would have to be studied on the lines so profitably employed in recent years in connexion with bacterial variation. The fact that human variola could, though with difficulty, be made to yield a variant pathogenically similar to fully adapted cow-pox, and like it capable of conferring immunity to small-pox, had been one of the strong arguments in support of the view that cow-pox was not an independent clinical entity and the result had been to ignore cow-pox as a mere side issue. But cow-pox could not be ignored or forgotten, for it was still with us; in quite recent years reports had been received of cow-pox prevalence in Austria and in Holland.

According to Dr. Kaiser, of the Vienna Lymph Station, there was now as in the past great difficulty in getting information about cow-pox, since farmers feared to declare its existence lest the sale of their milk should be prejudiced. It was only when the milkers contracted troublesome vaccinal lesions on their hands and arms that attention was drawn to the underlying cause. These lesions were of interest from two points of view. Though the commoner ones were vaccinal in type, there occurred also hard chronic cherry-red nodes which would seem to have an entirely different aetiology and were possibly to be related to the peculiar paravaccinia lesions described by Pirquet in 1915 as occurring particularly in revaccinations and believed by him to be due to an entirely independent virus. The point of interest in the milkers' lesions of the frankly vaccinal type was the fact of their occurrence in vaccinated persons. It was noteworthy that neither Kaiser in Austria nor Frenkel in Holland was able to assign a possible origin of any of these recent outbreaks of cow-pox in recent human vaccination. In spite of his absolutely negative findings in this respect Frenkel still expressed his adherence to the

belief that most cases of natural cow-pox are due to infection from newly vaccinated men. It would almost seem that there was a sort of conspiracy to bolster up the conventional view that cow-pox is not a disease *sui generis*. Personally Prof. Ledingham considered the matter entirely non-proven and so far as the epidemiological and circumstantial evidence in support of the secondary origin was concerned, it seemed to him extremely weak. That cows and horses could be variolated with difficulty or vaccinated with ease could not be used as a strong argument against the spontaneous origin of horse-pox and cow-pox if the circumstantial evidence was faulty, and it was here that he suggested tentatively a way out of the impasse. The mere fact that variola, cow-pox, and horse-pox could be made to throw off a type of variant possessing apparently similar properties—in fact, a sort of least common denominator which was designated *vaccinia*—in no way indicated identity of constituent antigen in the serological sense. The methods so far applied to the determination of affinities between clinically allied viruses, such as cross-protection or mutual neutralisation of response with the corresponding antiviral sera, could at the best afford evidence only of some definite community of antigen. On this basis variola, cow-pox, and horse-pox would be closely related, but Prof. Ledingham considered the experimental evidence supporting affinities between variola-vaccine on the one hand and sheep-pox and fowl-pox on the other to be far from satisfactory. He had no experience of sheep-pox, but so far as fowl-pox was concerned his own work yielded no evidence whatever of cross-protection between *vaccinia* and this disease of the fowl. It was possible that antiviral serum, which was largely used in work of this kind, might bring to light only broad affinities between virus antigens, whereas immune sera prepared from the pure elementary bodies of these pox diseases and used in agglutination and agglutinin-absorption techniques might yield much finer distinctions. The time was ripe for a great extension of this kind of work in elucidating affinities between viruses.

In conclusion Prof. Ledingham referred to the overwhelming advantage possessed by the comparative pathologist of the present day over the pioneers of a century ago in his armamentarium for the application of the experimental method. Supporting that armamentarium was the lore of the cell and the completely new outlook given by the development of bacteriology. These helps the pioneers had to do without, but could it be said that their work suffered very greatly in its intrinsic value on this account? Prof. Ledingham thought not. When one read, for example, the masterly clinical studies of an infectious disease by men of the standing of Robert Ceely one could not fail to be deeply impressed by their highly cultivated powers of observation, their capacity for reasoning from clinical premisses, and by the leisurely preparation of their published work in English undefiled. He sometimes felt that the very facility of the experimental method in these modern times was too often reflected in the premature publication of undigested or misinterpreted experiment. On the other hand, too often the morbid anatomist and histologist failed to realise how necessary it was for him to apply the experimental method wherever possible if his work was to interest a generation that craves for experimental demonstration. The experimental pathologist could usually be recognised from his methods of attack on problems and an outlook that came from constantly realising

and satisfying the widest implications of experiment. He quoted for their encouragement some words written by Robert Ceely, surgeon to the Buckinghamshire Infirmary, in the year 1842. "The knowledge of the diseases of animals, when it becomes more advanced, will contribute to diffuse new light on the diseases of man and perhaps bring to perfection methods of cure and prevention owing to the facility of multiplying on the inferior animals experiments which we cannot attempt in man. In the department of comparative pathology comprehending the exanthemata much remains to be accomplished, notwithstanding its diligent and successful cultivation in some parts of the continent since the time of Jenner. What has hitherto been effected there cannot suffice, however, to supersede, much less to paralyse, the efforts of his countrymen. But they must arouse themselves and no longer exhibit a practical indifference to the researches to which he so successfully devoted the energies of his great mind." They could, he thought, at a century's distance from Ceely's time, truthfully and thankfully say that the edifice whose foundation was laid by Jenner was still in the hands of the decorators.

SECTION OF NEUROLOGY

Dr. F. G. GOLLA in a presidential address delivered to this section on Oct. 17th on the

Nervous System and the Organic Whole

emphasised the necessity for a much more comprehensive view of nervous activity than that afforded by physiology. He pointed out that mechanical conceptions of nervous function are applicable to macroscopic entities alone and that the micro-mechanics of pure physics cannot be used in the elucidation of organic activity. Since the reflex studied in isolation is a physiological abstraction, he argued that attempts to account for nervous activity in terms of reflex integration are fallacious; that the unit of function, if it can be differentiated, is not the reflex arc but a mechanism which is governed by the sum of the resultant stresses of the rest of the nervous system. He defined the nervous system not as a passive organism only responding to changes in the internal and external environment but as exhibiting in itself a state of autogenous activity. If it was to be regarded as a mechanism it was one that acts as a whole, whose activity is autogenous but modified by the totality of the environment, whose lability is very great but still directed as a whole towards certain modes of reaction. Dr. Golla pointed out that the nervous system considered apart from its history was an abstraction; every existing object whether at rest or motion is a strand of history with some duration. Activity whether considered in relation to the nervous system or its environment could never be recapitulated. Again, no account of the nervous system could be other than an abstraction that did not envisage its relation to mental events. Theories of the relation of mind to body were not discussed by Dr. Golla, but all arguments were, he said, based on the brute fact, verifiable by the evidence of normal and pathological psychology, that mental events are invariably accompanied by related nervous events. Since we are aware of purpose in initiating and continuing certain chains of activity he argued that some physical correlate of purposive direction must accompany the corresponding nervous function. A teleological activity was thus postulated for nervous activity

from considerations based on the holistic view of nervous function. The objections to teleological theories in science were also dealt with by Dr. Golla; as he pointed out, the views he advanced were distinguished from the old teleology in that final causes were not contemplated. The orientation of the total activity of the organism was not determined by finality. He claimed that the views advanced would, by considering nervous function in relation to the organic whole, make intelligible many forms of nervous activity which, considered by themselves, are meaningless.

SECTION OF MEDICINE

At a meeting of this section held on Oct. 22nd the chair was taken by Sir CHARLTON BRISCOE, the president, and Dr. ARNOLD STOTT opened a discussion on the

Recognition of Myocardial Deficiency

He said that increasing attention was being paid to the myocardium in gauging the severity of heart disease and in prognosis. The aetiology of chronic heart disease should be determined at the outset of every case. The commonest cause was rheumatism (32 per cent.), closely followed by hypertension (30 per cent.) and arterio-sclerosis (25 per cent.). Rare causes were syphilis (4 per cent.) and thyrotoxicosis (3 per cent.). Rheumatic infection was practically the only cause under the age of 30, and it appeared as chronic valvular disease, especially of the mitral valve, with some enlargement and, in most cases, eventual auricular fibrillation and congestive heart failure. Syphilis usually started as aortitis spreading to the aortic valve, followed by gross enlargement of the left ventricle. Often there was obstruction of a coronary artery with angina or infarct. Rarely there was a diffuse syphilitic myocarditis or gumma producing heart block. Hypertensive heart disease was important in later life and usually of the "essential" type, though in about 5 per cent. of cases it followed chronic nephritis. There was a varying degree of enlargement, and congestive heart failure was a common ending. Arterio-sclerotic heart disease was recognised by angina pectoris or infarction from coronary thrombosis. Angina might be present without other signs of cardiac disease. Thyrotoxic heart disease was characterised by palpitation and dyspnoea, and later by auricular fibrillation terminating in congestive heart failure. The eye signs and thyroid enlargement might be very slight. Surgical treatment was often successful. Certain symptoms helped in the recognition of all these types. Dyspnoea was the most important, appearing on a degree of exertion not previously causing distress, and resulting from an insufficient output of aerated blood to the respiratory centre. It was progressive to orthopnoea, and was invariably present in those types in which congestive heart failure eventually appeared. An entirely different dyspnoea was cardiac asthma, a sure sign of severe myocardial disease; this occurred in paroxysms, usually during sleep, and was believed to be due to sudden left ventricular weakness causing engorgement of the lungs. It was common in hypertension and might be the first symptom. Cheyne-Stokes breathing was often present in the later stages of grave myocardial disease. Anginal pain was not usually agonising or associated with a "sense of dissolution," and was too often labelled indigestion. It was particularly noticeable on hurrying

after a meal, and was often accompanied by aerophagy.

The most important physical sign of myocardial deficiency was enlargement, which was not only a response to increased work. The simplest clinical method of estimating it was the position of the apex-beat. Radiology was a great help in determining this, but percussion was crude and seldom of much use. Diastolic murmurs were more important than systolic and involved a strain on the heart; but the heart had enormous reserve power and the significance of valvular disease lay in the likelihood of simultaneous damage to valves and myocardium. Pulsus alternans and gallop rhythm were signs of grave damage, as were also persistent auricular fibrillation, auricular flutter, and complete heart block. Paroxysms of tachycardia were functional disturbances not necessarily resulting from myocardial damage. Signs of overfilling of the venous system should be sought in cases of dyspnoea or suspected heart disease; the tell-tale jugular veins should never be overlooked. Slight distension in the recumbent position might be a valuable early sign.

Thymias, tachycardia, and certain signs unobtainable by other means; in some cases it brought certainty where the diagnosis would otherwise be in doubt; but it seldom gave more than confirmatory evidence of myocardial disease. The most valuable diagnostic points were dyspnoea, pain, enlargement, certain murmurs and disorders of rhythm, and the evidence of overfilling of the venous system.

THE CHIEF DIFFICULTIES IN DIAGNOSIS

Dr. D. EVAN BEDFORD said that the detection of hypertensive cardiac disease depended largely on symptoms. The common error was not so much to overlook myocardial disease as to diagnose it when it was not there. Dyspnoea might simulate it in cases of emphysema. A barrel-shaped chest was not important in emphysema but restricted expansion of the lung was, and radioecopy was a great help. Secondary changes in the heart occurred in a few cases, but actual heart failure was very rare and almost invariably accompanied by obliterative changes in the pulmonary vessels. Pulmonary fibrosis might closely simulate the dyspnoea of heart disease, as might also cancer of the bronchus, which was a not uncommon cause of severe dyspnoea. Diffuse secondary carcinomatosis might cause fine fibrosis with pronounced dyspnoea and perhaps persistent tachycardia—apparently reflex—but few physical signs. Mediastinal tumours sometimes caused difficulty as in the early stages they might only be recognisable by X rays. Intrathoracic goitre was an important cause of dyspnoea, tachycardia, and heart failure. A rare cause was obliterative pulmonary endarteritis. Nervous dyspnoea was often attributed to the heart; it was associated with a peculiar sensation of air-hunger and sighing respiration. Abdominal obesity was a common cause of severe dyspnoea, as it elevated the diaphragm. Full radiological and other investigations were necessary for the diagnosis of myocardial disease. Left mammary pain was often put down to heart disease. It was a dull ache radiating to the angle of the left scapula or down the left arm. Radiation down the right arm was rare in this nervous type and was therefore of greater diagnostic aid in angina than radiation down the left arm. Pain in the breast

should never suggest heart disease. Aneurysm, sub-sternal goitre, and mediastinal tumour might cause pain but were revealed by radiographic examination. Para-oesophageal hernia was a rare cause of angina-like pain. Syncope was not a common symptom in myocardial disease. Faints beginning in middle life suggested cerebral rather than cardiac disease. Vaso-vagal attacks might be alarming and cause diagnostic difficulties, but the history and perfect recovery between attacks were diagnostic. Tachycardia alone was not a reliable evidence of myocardial disease; nor were extrasystoles. Ventricular paroxysmal tachycardia was of more serious omen than other types. Auricular fibrillation or flutter usually indicated myocardial disease, but oedema was only evidence if associated with other signs such as filling of the cervical veins. Exhaustion and giddiness should not suggest heart disease. Systolic murmurs and alterations in the first sound were of little help. Myocardial disease should never be diagnosed on heart sounds alone, with the possible exception of gallop rhythm.

Systematic investigation must be made to discover the cause in every case. A routine Wassermann was of advantage, especially if there was cardiac pain, and X rays of the aorta were useful. The condition of the aorta was a very good indication of the condition of the coronary arteries. Coronary disease was recognised largely by exclusion; almost all patients had had pain or dyspnoea before mortal syncope occurred. The electrocardiogram was of great value in confirming the diagnosis. Chronic constrictive pericarditis was a rare cause of heart disease.

FATTY INFILTRATION

Dr. A. G. GIBSON said that fatty infiltration was a factor which might be found in minor degrees at all ages and not only in the obese. The wall might be almost wholly replaced by fat, and fat might be found under the endocardium in severe cases. Muscle bundles were pushed away. These cases did not generally come to the cardiologist or physician. In 300 routine post-mortem examinations there had been 116 (38 per cent.) cases of fatty infiltration. In life the patients had shown irrelevant disorders (gastric, cerebral, and renal) in 42 per cent. Death had been sudden and unexpected in 13.7 per cent.; reduced to 10.3 per cent. if four cases of ischæmic necrosis were excluded. There had been five anæsthetic deaths, and other cases of sudden unexpected death, some before and others after operation (15.7 per cent. followed operation). In a group of cases (18.9 per cent.) fatty infiltration had been associated with accident, and in 8.6 per cent. there had been heart disease as well. One patient who had died suddenly had been attended regularly for "myocarditis," but there had been no post-mortem cardiac lesion other than fatty infiltration. This condition added a factor of stress when there was a heart strain such as operation or accident, and might cause signs of heart failure.

DISCUSSION

Dr. B. T. PARSONS-SMITH thought that the back-pressure theory of heart failure was rather discredited nowadays in favour of the diminished output theory. Recent work had shown that the failing heart had only a very slightly diminished output, and the back-pressure theory was worthy of consideration. Congestion of the lungs might play some part in dyspnoea. Reflex impulses from lungs, heart, and muscles might also be important. The blood in early heart

failure showed no deficiency of oxygen and no increased acidity or carbon dioxide content.

Dr. LOEWY (Vienna) said that if a sample of blood were taken from a dyspnoic patient and compared with the normal it would always show a much darker colour if emphysema were present. This was a useful test for the exclusion of emphysema as a cause of dyspnoea.

Dr. K. HARRIS thought the risk of diagnosing angina in cases of indigestion was greater than the converse. He inquired the importance of the T wave in myocardial degeneration.

The PRESIDENT said that two symptoms were of importance: unexpected fainting in an elderly patient, and sallowness. A number of organs had a direct inhibitory effect on the tone and level of the diaphragm and caused excessive movement of the chest of which the patient was very conscious. The stomach had this effect, as had also the heart and the gall-bladder. A contrary effect was produced by distension of the colon, which lowered the diaphragm. There was an alteration in the outline of the chest and upon this depended the pains found in these conditions.

Dr. SHIRLEY SMITH mentioned the significance of a new appearance in late life of any symptoms which might suggest the cardiovascular system. Anginal pain often had a relationship to food, but nervous left-mammary pain had not.

Dr. H. S. STANNUS spoke of the frequency of certificates of "cardiac debility" and wondered if these cases were all anxiety neurosis, and mentioned the frequency of heart symptoms in gall-bladder disease.

Dr. STOTT, in reply, said he was quite unfamiliar with the appearance of fatty infiltration in cases of sudden death. He did not regard a diminished output of oxygenated blood as the sole cause of dyspnoea, which was not a simple question. The sallowness mentioned by the President was especially associated with coronary disease and was very difficult to explain.

Dr. BEDFORD, also in reply, thought it was unscientific to base prognosis on inversion of the T wave or any other single finding. Only experience could teach when to rely largely on the electrocardiogram, which should in any case be regarded as a diagnostic rather than a prognostic instrument. Faints first appearing in middle or later life were serious, but for the brain rather than the heart, he thought. Influenza did not lead to cardiac disease but rather to disturbances of the autonomic nervous system.

Dr. GIBSON, replying to Dr. Stannus, commented that surgeons regarded gall-bladder cases as especially liable to heart complications, and fatty infiltration was often found in gall-stone cases.

NEW SUN RAY CLINIC AT BEDLINGTON. — Mr. Godfrey Nicholson, M.P., on Oct. 12th declared open a new sun ray clinic and child welfare and maternity centre at Bedlington, Northumberland. The centre is a fine single-story building, and in the sun ray department equipment of the latest type is installed.

ROYAL HAMPSHIRE COUNTY HOSPITAL. — This institution has launched an appeal for £30,000 to commemorate the bicentenary of its establishment. Said to be the first hospital to be supported by voluntary contributions set up outside London, it was founded in 1736. In 1865 larger accommodation was required and the present site of the institution was selected by Florence Nightingale who personally supervised the planning.

REVIEWS AND NOTICES OF BOOKS

Injury and Incapacity

With special reference to Industrial Insurance.
By H. ERNEST GRIFFITHS, M.S. Lond., F.R.C.S.,
Surgeon, Albert Dock Hospital. London: Baillière,
Tindall and Cox. 1935. Pp. 270. 12s. 6d.

In the preface to this useful work Mr. Griffiths comments on the remarkable differences of opinion expressed in the law courts by medical witnesses asked to give a prognosis in cases of injury. It is of interest that the hospital surgeon generally gives a much more favourable prognosis than the patient's panel doctor. This does not necessarily represent any real divergence of view, but only means that the surgeon bases his prognosis on the length of time before the patient will be discharged from hospital, while the panel doctor estimates the period during which he will have to give certificates that the patient is still unfit for work. In order to arrive at a basis of prognosis for each disability discussed in this book Mr. Griffiths deemed it necessary to trace the history of a large number of cases from the date of injury to the time of resumption of full work. He was reluctant to use hospital figures on the grounds that the records of any one hospital must depend on the type of work in the neighbourhood, and also upon the skill of individual surgeons. It was therefore decided to obtain the figures through an insurance company, and by the courtesy of one of the largest companies in this country, which deals mainly with claims arising out of the Workmen's Compensation Acts, facilities were provided for analysis of 50,000 consecutive cases of accidents. After the first 10,000 of these had been analysed it was found that a sufficient number of certain injuries had been obtained, but where there was any doubt the whole series was investigated. For example, no cases of cut finger were examined after the first 10,000, but every fracture occurring in the whole group was tabulated. In addition to this analysis Mr. Griffiths has been able to utilise his own large experience in the treatment of injured workmen and in the determination of their working capacity. From a study of these records he has drawn up tables of average periods of incapacity for both heavy and light work consequent upon various injuries.

The main part of the book is divided into twelve chapters dealing in turn with disabilities resulting from injuries to the head, chest, back, abdomen; from fractures of the upper and the lower limb; from injuries to nerves and muscles; and from dislocation and diseases of the joints of the upper and the lower limb. The last two chapters concern amputations and miscellaneous injuries. The second part of the book is perhaps even more valuable. Here are described the maximum degrees of disability compatible with efficient work in twenty-four skilled and unskilled occupations. It is interesting to learn, for example, that shortening of the forearm or an inability to rotate it more than 15° in either direction constitutes no disability in a navvy, and that a lorry driver may still be looked upon as fully effective despite flat-foot or a left-footed Syme's amputation. An index of occupations follows which indicates the type to which each class of work belongs, and is the more useful because it contains many crafts which will be unfamiliar to most doctors—for instance, on the first page alone, aerographers, back-tenters, backwash minders, greasy birlers, and Berlin blackers.

The index is occasionally inaccurate and in the chapter on spinal injuries no mention is made of spondylolisthesis, although trauma must frequently be a factor in producing this condition. Otherwise the book defies criticism. It is simply and lucidly written, and should be as comprehensible to the intelligent layman as to the doctor. Everyone who has to deal with that distressingly prevalent malady "compensitis" should have this book at hand for reference.

Textbook of General Bacteriology

Eleventh edition. By EDWIN O. JORDAN, Ph.D.,
Professor of Bacteriology in the University of
Chicago and in Rush Medical College. London and
Philadelphia: W. B. Saunders Co., Ltd. 1935.
Pp. 825. 25s.

THIS book has found a niche of its own among the better text-books on bacteriology. It contains an adequate but not too detailed account of medical and public health bacteriology written from a broader point of view than are most medical text-books on the subject; thus there are excellent chapters on the nitrogen cycle in nature, on bacteria in the industries, and on bacteria in connexion with plant diseases. These chapters are very useful, since they arouse in the medical student an interest in the more general problems of microbiology. The broad outlook of the work also makes it one of the best of introductions to medical bacteriology for students of agriculture and kindred subjects who have already approached bacteriology from their own point of view. The new edition has been brought well up to date; among the revised chapters that on food poisoning is particularly good.

A Complete Physics

Written for London medical students and general use. By W. H. WHITE, M.A., B.Sc., Senior of the
Lecturers and Examiners in Physics in the Medical
Schools of London. London: Richard Clay and
Sons, Ltd. 1935. Pp. 848. 15s.

THIS is indeed a remarkably complete text-book on physics for medical students. It covers 848 pages, contains 420 diagrams, and is interspersed with 1000 examination questions. A study of the index will convince the reader that no part of physics is neglected. But the author puts a question just before the list of contents: "Behold, there were very many . . . and lo, they were very dry. Can these bones live?" They can indeed and they do. Besides being comprehensive this is a lively book, full of sound information leavened by good fun and even wit.

Apart from the general excellence of the text the book has another source of attraction—the affectionate regard manifested by the author for the struggling student. This is exemplified in the three-page valedictory on the subject of examinations:—

"Some of you can't help being nervous; so far as we are concerned there is no cause for it, what we cannot allay we try to allow for: the awful divinity that doth hedge a visiting school examiner we have outgrown: we be your elder brethren, glad enough to welcome youngsters into the family, only putting back those who, as yet, have over-estimated the natural gifts of their youth . . ."

The text ends with a Frater Vale, and a photograph exhibiting the bright humour of an author who is certainly serving youth well by this book.

THE LANCET

LONDON: SATURDAY, OCTOBER 26, 1935

THE PREVENTIVE OUTLOOK

Dr. W. G. SAVAGE in his presidential address last week to the Society of Medical Officers of Health criticised some present tendencies in the public health service. It was more than thirty years ago that he joined that service because he believed in preventive medicine, and he was, he said, still the true believer from whom criticism comes best. The work of the M.O.H. was less interesting and less stimulating than it was before the war, and it was likely to become even less so. In the larger areas the medical officer of health would soon be forced to be almost entirely an administrator, a master of experts in all subjects but expert in nothing himself. This tendency had been accentuated by the Local Government Act of 1929, by which the medical officer of health became an administrator of beds, largely occupied by the end-products of disease, and a supervisor of defectives—in a word, “largely enmeshed in functions which are not our proper business.” He would not go so far as the late Dr. F. E. WYNNÉ did in 1922 when he wrote of “the wrong turning” in public health, but they were being induced and officially directed to squander energies by incursions into side roads, progress to the real goal being deplorably slow. It may be interpolated here that the Ministry of Health is party to a wide liberty in the way the annual reports of medical officers of health are drawn up. In a circular just issued, while it is stated in general terms that the report for 1935 should be limited to a record of alterations, improvements, or developments which have taken place during the year, specific request is made for an account of any noteworthy conditions prejudicial to the health of the area which have not been adequately dealt with in previous special reports, and it is open to the medical officer to discuss in any report a special subject of importance to the health of his area.

The law as it affects public health is at the moment in a state of flux, for, as indicated on another page, the codification of enactments under which the medical officer of health does his work has been completed and there is no reason why a new Act should not soon be placed on the statute book which will facilitate reference and help to lubricate progress. One of the chief difficulties in putting preventive medicine into practice is the inflexibility of the law. It was, Dr.

SAVAGE said, often made a ground of reproach that the findings of science were not more quickly applicable to public health practice, that the lag period between ascertainment and enforcement was too long. He himself holds the opposite view, believing that as laws are now made the tendency is to apply findings before it is known that they are really applicable. Of this he gave a striking example: vast sums had been spent on isolation hospitals which would never have been spent in that form if our present knowledge had been available. But the law is the law, and a vested interest springs up around it with a strong bias to perpetuate what exists. While hypotheses are the breath of life to science, no scientist would go to the stake for a hypothesis; and while welcoming the practice of making innovations in public health permissible and adoptive, Dr. SAVAGE would only have this done where the findings can be studied and tested in a spirit of research. Adequate scientific controls, that was the urgent need in public health work to-day, and that, he said, means an adequate staff. Long overdue is the detailed study of morbidity; we require statistics of diseases as much as we need statistics of mortality. Dr. SAVAGE looks for a wide extension of compulsory notification in selected areas under controlled conditions, so that we can learn something about their distribution, age onset, incidence upon various sections of the community, and relation to other morbid factors. What do we know of disease that only death-rates know?

More time to think and more knowledge to oil our thinking brought Dr. SAVAGE to the question of skilled lay assistance to preclude the medical officer of health from wasting his time on problems for which he was never trained. Lay administration had its own dangers, the chief being inelasticity. But if to his other training the medical officer of health added a training in scientific administration he should be able to shed much of his present burden of pure administration and turn to more significant matters. There was dissatisfaction too among the younger men who had entered the service hopefully but had found their actual duties bore little relationship to the larger problems of public health. So many routine examinations, so many processions of children for whom they could only give advice and not treatment. Every service required constant revision; with adequately trained infant visitors most of the work now done at the centres could be done in the homes, while much of the school inspection and maternal welfare should be transferred to the private practitioner. This would serve to shorten the long disheartening road from the D.P.H. to the M.O.H. Developments along these lines should increase the interest of the work of the junior members of the service and help to preserve that freshness of outlook which would counteract the tendency of the senior members to sink into ruts. The thread running through Dr. SAVAGE'S whole discourse was insistence upon the fluid and dynamic nature of the health officer's work and its preventive outlook.

TUBERCULOUS MENINGITIS

SEVERAL of the more obvious problems of tuberculosis of the nervous system remain unsolved. Conspicuous among them is the relation of tuberculous meningitis—the predominant clinical manifestation—to miliary tubercle and to the focal deposits which attract less attention during life but are more easily demonstrable post mortem. Two years ago we reviewed this subject¹ with particular reference to the work of V. P. JOUKOVSKY and V. N. ROUSSIKH, and the varied types of focal lesion they demonstrated in the nervous system. Since then there have been many further contributions and some of the writers have exposed new aspects of old problems. It is noticeable that of late investigation has been directed as much to adults as to children; and in at least two directions some advance seems to have been made—on the pathogenesis of tuberculous meningitis and on the possibility of recovery from it. But inquiry along these lines has brought into prominence a difficulty which has been insufficiently appreciated—the difficulty of making a certain diagnosis during life.

During the present year studies on cerebral tuberculosis in children have been reported by BLACKLOCK and GRIFFIN² in this country and by MORRIS SIEGEL³ in the United States. The former tabulate the post-mortem findings in 241 children, and it is particularly interesting to read the account of 45 cases in which tubercle bacilli were isolated from the cerebro-spinal fluid during the illness. In all but one of these meningitis was found; in eight it was associated with tuberculomata. But the single case in which general miliary tubercle and tuberculomata were unaccompanied by meningitis is of no little significance, for the signs and symptoms had led to a diagnosis of meningitis, and the fluid had been lethal to the guinea-pig. As BLACKLOCK and GRIFFIN suggest, some reported cases of recovery may well have been of this kind. In reviewing the subject of pathogenesis SIEGEL endeavours to correlate the results of animal experiment with those of clinical and pathological observation. The consistent failure of attempts to produce meningitis in animals by any means other than subarachnoid inoculation suggests that bacillæmia is not the immediate cause of meningitis—a conclusion in accordance with the findings in very young infants (1-2 months). In early infancy general miliary tuberculosis is found, but never meningitis, and seldom macroscopic tubercles; the child dies of toxæmia before cerebral foci have had time to develop. At a slightly later age a few isolated tubercles may be found in the brain and meninges, and meningitis may also occur. The delay in the appearance of meningitis is attributed to “the difficulty of getting enough free bacilli into the intermeningeal spaces.” It seems probable that infection of the

blood stream produces at first only isolated tubercles, as asserted by RICH and MCCORDOCK. On the other hand meningitis may undoubtedly arise by extension from isolated foci in the absence of general miliary tuberculosis. In a detailed account of their researches in France BOQUET and BROCA⁴ confirm some of these observations. They found that meningitis was easily produced in rabbits by subarachnoid inoculation not only with active tubercle bacilli, but with BCG or killed bacilli. After intravenous injection organisms could be obtained from the brain, but meningitis never developed.

Also in France, ROGER⁵ draws attention to certain characteristics of tuberculous meningitis in adults in whom, he says, the convulsive element is absent and the morbid process more localised but less typically basal. In a careful description of the symptomatology in adults he lays special emphasis on the subacute course and on the frequency of psychic disturbances which may complicate the diagnosis. He is convinced that treatment by Jousset's “allergine” has achieved success and is worthy of trial. ALLAN WALKER,⁶ of Sydney, brings out the fact that in adults meningitis is by no means always a manifestation of general miliary tuberculosis. Tubercles are always to be found, but are not a prominent feature of the pathology. Most characteristic are the highly gelatinous exudate and “a tendency to necrotic change of slight but definite degree, a tissue spoiling which is probably not wholly dependent upon vascular change.” WALKER draws an interesting analogy between these processes and “epituberculous” pulmonary affections. He suggests that the course of the disease is divisible into three stages: first, blood insemination with tubercle-formation; secondly, sub-pial infection; and lastly, massive meningeal infection with formation of exudate and local softening. Such cases as recover have probably not reached the third of these stages.

The question of recovery from tuberculous meningitis is intimately related to that of pathogenesis. HOBSON⁷ in our own columns recently described the case of a man of 24 who had signs suggestive of tuberculoma of the posterior fossa; in addition there were neck rigidity, fever, and vomiting, and tubercle bacilli were found on three occasions in the cerebro-spinal fluid; yet within four months he had made a complete recovery, and he was in good health five months after discharge. HOBSON suggests that a pure tuberculous meningitis had been present, but was localised to the posterior fossa. Like the work already mentioned his case record shows the difficulty of interpreting apparent recovery from tuberculous meningitis. What exactly has the patient recovered from? Are there any means of deciding conclusively during life that a person is suffering from true tuberculous meningitis? Clinical observation cannot establish the diagnosis;

it can only detect the signs of meningeal irritation. The physician relies for confirmation on certain changes in the cerebro-spinal fluid, and it may be that the interpretation of these changes needs reconsideration. In BLACKLOCK and GRIFFIN's case to which we have referred the fluid showed "a low count of cells, chiefly lymphocytes, and a positive Pandey reaction," and was lethal to the guinea-pig; unfortunately no mention is made of the chlorides. It came to autopsy, but no meningitis was present. In HOBSON's case the diagnosis of meningitis was undoubtedly justified according to the customary criteria. In the fluid both polymorph and lymphocytic cells were present, though the count is not given; the chlorides fell on one occasion to 550. We are left with the salient fact that of cases in which the cerebro-spinal fluid shows changes like these an overwhelming majority are rapidly fatal. It remains to be discovered what circumstances account for the few fortunate exceptions.

THE ASSESSMENT OF NUTRITION

THE decision of the Health Organisation of the League of Nations to continue and develop its investigation of nutritional problems renders it doubly urgent to define what malnutrition is. Our own Board of Education, as is noted in another section of this issue (p. 968), relies on the impression of the school doctors, which leaves room for wide divergence of opinion. No index of nutrition has met with general acceptance. In most indices—and their name is now legion—weight has been one of the factors employed, while many other measurements—height, body circumference, thickness of the abdominal fold—have been used in the search for a constant to indicate the same state of nutrition at different ages and heights. The simple index, height divided by weight, has been replaced by the weight divided by the square or the cube of the height, and in fact all varieties of multiples, divisions, and additions have been propounded. These more sophisticated constants, however, appear to have very little in their favour, since it has been shown that the simple ratio, W/H , is just as highly correlated with the assessments of nutritional status by experienced clinicians as are the more elaborate ratios, W/H^2 for example, at least at ages under 5.¹ On the other hand it can be argued that any index comprising weight as the main factor is unsatisfactory. Heavy children may derive their weight from a large frame which is, in fact, inadequately covered, while light-weight children may be well-nourished and owe their low position on the scale to a smaller frame. In an attempt to avoid such difficulties RAYMOND FRANZEN and GEORGE T. PALMER, working for the American Child Health Association, introduced last year a new index of nutritional status for children of 7 to 12 years of age, which, from its components, they named the ACH index.² This index is based on three simple measurements—

namely, arm girth, chest depth, and hip width—its object being to measure soft tissues in relation to body-build. The authors claim that it selects three-fifths of extreme defect cases compared with only one-fifth by the weight-height-age method used in a comparable manner. A recent test of its efficacy is reported by C. LOUIS LEIPOLDT³ who has applied it to 600 white and 400 native and coloured schoolboys in South Africa. The application itself is simple. Two arm measurements are taken round the upper arm, one with the arm flexed and the tips of the fingers resting on the shoulder, the second with the arm hanging loosely at the side. The chest measurements are taken antero-posteriorly with the child breathing normally; inspiration and expiration excursions are measured, and their sum is the chest-depth measure. The hip measurement is taken between the great trochanters. To apply the index the chest-depth measure is subtracted from the sum of the two arm measurements, and the difference is related to the width of the hips. FRANZEN and PALMER provide a table in which is given, for different widths of hips, the minimum difference allowable for good nutrition between the arm girth and chest-depth measurements. If the difference observed in an individual is less than the figure given in the table against the appropriate width of hips, then that child is selected as malnourished. LEIPOLDT reports favourably upon this method. His groups were first assessed by clinical methods and the proportion undernourished was found to be very high—39.8 per cent. of 500 white boys, 55.7 per cent. of 300 coloured boys. On applying the ACH index 32.8 per cent. of the white boys and 62.0 per cent. of the coloured were selected as undernourished. The test was also applied to boys attending a clinic, of whom nearly everyone was clinically assessed as malnourished—viz., 91.4 per cent. of the white, 92.7 per cent. of the coloured. The ACH index gave 78 and 94.5 per cent. for these groups. Though evidently this method may overlook many cases of malnutrition, yet it seems to have merits as a simple selection test which can readily be applied by any lay examiner. More information than is given here, however, is desirable. For instance, it has to be presumed that the 32.8 per cent. of white boys selected by the ACH test all belonged to the 39.8 per cent. clinically assessed as undernourished. It would also be interesting to learn what type of malnourished boy the test failed to select—i.e., does the missing 7 per cent. comprise only those on the borderline by clinical assessment or include some of the grossly undernourished? The fact that an index based upon American boys is apparently applicable to those of South African certainly suggests that its inventors have hit on a fundamental standard.

A further test of the method is being carried out in South Africa by I. FREED whose preliminary work at Veldrift, C.P., has led him to express considerable dissatisfaction with the height-weight-age method of assessing nutrition.⁴ The 300

children whom he examined had, according to the results of a questionnaire, a "monotonous and deficient diet," rich in carbohydrate and protein but short of fat and vitamins. Their home conditions also left much to be desired, for on the average there were 3.83 persons per bedroom, 2.04 persons per bed, and only 17.7 per cent. of the children slept alone. In average weight at each age these children are distinctly below the American and English figures FREED takes for comparison, but they do not differ appreciably from the figures for children at the Transvaal Memorial Hospital who would presumably from the genetic standpoint form a more satisfactory standard of comparison, though a hospital population can hardly be regarded as normal. Viewing these children with a clinical eye FREED says they have slender, wiry frames and are strong though lean. Their heights and weights give, he concludes, little indication of their nutritional status. It will be interesting to see how the ACH index classifies them.

NEW OPPORTUNITIES FOR RESEARCH ON THE NERVOUS SYSTEM

MEDICAL research in England owes much to American support. Of late years we have drawn help from the United States not only in money but in inspiration, and nowhere has this inspiration been more valuable than in neurology and psychiatry. It is with great pleasure therefore that we record two further gifts by the Rockefeller Foundation which will substantially improve facilities for work on these subjects in London.

The first, and larger, is made to the hospital of HUGHLINGS JACKSON, the master of neurology, whose birth centenary we have been celebrating this year. JACKSON based his philosophical studies on observations made at the National Hospital, Queen-square, and here there has developed a nucleus of workers whose names are rightly renowned. From this hospital, originally occupying only a single house in Queen-square, knowledge of the intricacies and the disorders of the nervous system has spread throughout the world; it is recognised as one of the great schools of neurology where post-graduates seek instruction and where research, despite all obstacles, is continually pursued. The obstacles, none the less, are considerable; the buildings have long been inadequate for carrying on the teaching and investigation. A scheme has accordingly been drawn up for new ones which will include sufficient teaching rooms and laboratories, with special wards and a new surgical department, and towards the expenses of their construction the Rockefeller Foundation has generously offered £60,000, provided that the hospital authorities can collect the rest. This means that £120,000 will have to be raised by public subscription in this country, and an appeal is issued this week. Given the new facilities, the Queen-square workers will be able to continue their important studies, notably on the histopathology of the nervous system in its relation with clinical problems, and the opportunities for bio-

chemical investigation will be greatly enhanced. In view of the necessity of approximating laboratories to wards, the plans include accommodation for 27 beds, in several wards, where special observation of patients may be undertaken. Linked to these wards are physiological laboratories in which the most advanced methods for physiological investigation will be available, and simultaneously the surgical department is to be rebuilt on a scale appropriate to the technique of modern neurosurgery. To obviate the risk that the laboratories once erected should not be used through lack of means the Rockefeller Foundation has offered an additional gift of £60,000 towards an endowment fund for research, this money to be available for the remuneration of workers within the laboratories. This grant is contingent upon the hospital board raising the funds required to complete the buildings before December, 1937, but there can be little doubt that the sums required will be raised as soon as the public really becomes aware of the implications of the appeal.

If the debt of neurology to the United States is great that of psychological medicine is in many ways even greater, and fruits of the scientific liaison with America are well seen at the Maudsley Hospital which also benefits by a new Rockefeller gift. Eight of the doctors who have been on the staff of this hospital have enjoyed the advantages of a travelling fellowship of the Rockefeller Foundation, and four others have had corresponding opportunities for study abroad made available to them by the Commonwealth Fund of America. It is not only in the furtherance of child psychiatry and social psychiatry in this country that the Commonwealth Fund has played a notable part, but also in its generous support of investigations in adult psychiatry; it has maintained at the Maudsley Hospital during the last four years no less than seven full-time research workers for periods of at least a year. Besides these grants, the hospital has had the Maudsley bequest, devoted to like purposes, and the assistance of the Medical Research Council. By such means the conditions were in part provided without which fruitful research is very difficult of accomplishment; the *Archives of Neurology and Psychiatry*, issuing from this psychiatric centre, has borne testimony to the many investigations which have been the outcome. They are the outcome also of the far-sighted generosity of the London County Council in fostering progress at the hospital: without its support such development would have been impossible. The considerable enlargement of the premises, now approaching completion, is further evidence of the determination with which this body continues to provide liberal facilities for research and teaching, as well as for the indispensable day-to-day work of treating the sick. Hence many of those who work in the hospital are not only in daily contact with the clinical problems of psychiatry but must as teachers review what is known or accepted in this branch of medicine, and as investigators seek to add to the common store. Those of them who have enjoyed a Rockefeller fellowship are indeed under a moral obliga-

tion to be so engaged, and the Foundation's addition of five research posts—four of them to be allocated to men who have held important appointments in Germany—is encouraging and welcome.

The field of mental and nervous illness is so wide and difficult that no benefaction can ensure the solution of its greater problems, no hospital regard itself as more than a unit of neurological research. It is nevertheless true that without adequate financial support much of the necessary work

could hardly be carried out, and that it is only at clinics which are fully staffed and equipped and also have access to a vast population, that the combination of trained investigators and suitable material for research is likely to be available. Much may be hoped from the work going on so actively at Queen-square and at the Maudsley, where circumstances have conspired to bring together men with experience in more than one country and familiarity with more than one branch of the subjects under study.

ANNOTATIONS

PSYCHOGENIC AMNESIA

POLICEMEN and casualty officers are not unacquainted and acquire some degree of familiarity with the forlorn creature, often dilapidated and travel-worn, who cannot recall his name and address or identify himself in any way. He shows no signs of recent concussion or convulsion, he seems in his senses, if somewhat bewildered, and his assertions bear the impression of genuineness. He may recover his memory before a psychiatrist has come on the scene, and he is usually reluctant to enter on a course of psychological treatment, if that be proposed. Often he turns out to have been in Queer street when his memory failed him so completely and, it may be said, opportunely. Sixty-three of these cases of psychogenic amnesia have been collected from the records of Bellevue Hospital in New York by Dr. Milton Abeles and Dr. Paul Schilder.¹ The sexes were equally represented if one ignores the homosexuality of four of the patients. The majority were adults who had not reached middle age, and the precipitating factor for the amnesia was almost always discovered to be some unpleasant social conflict, financial or familial. The attacks varied in duration, but few lasted more than a week. Recovery was spontaneous or was in some cases hastened by hypnosis, persuasion, free association, and other psychiatric devices. The authors, who indulge in the inevitable speculations about the oedipus complex, unfortunately do not discuss in detail the relation in time between the clearing up of the symptom and the ending of the situation that provoked it. It is often impossible to make any impression, by psychological or other treatment, upon the amnesia until external factors have ceased to make it profitable. This happens irrespective of whether the forgetting appears a deliberate effort to deceive, or is as obscure to the patient as any other typically hysterical mechanism might be. It is not only in hysteria, however, that fugues of this sort occur. The authors rightly point out that diagnosis must be made between psychogenic amnesia and a variety of conditions, including schizophrenia, manic-depressive psychosis, organic disease of the brain (including trauma to the head, epilepsy, cerebral arterio-sclerosis, carbon monoxide encephalopathy), and finally simulation; it is, however, possible to discover every feature of the psychogenic variety in patients whom one discovers to have an organic disease or a profound depressive syndrome. Although psychogenic amnesia, as it is commonly met with, may be taken, for therapeutic and didactic purposes, as a simple example of escape or "flight into neurosis," these latter instances serve to indicate

the incompleteness of purely psychological explanations of amnesia, and the occasional practical risks of accepting them as final.

WHERE IS SERUM PHOSPHATASE FORMED?

THE determination of serum (or plasma) phosphatase is assuming considerable importance as an aid in the diagnosis and treatment of certain bone diseases¹—such as Paget's disease, generalised osteitis fibrosa, osteomalacia, and rickets—and in the distinction between different types of jaundice.² This has brought to the forefront the question whether the serum phosphatase in the normal individual is derived almost exclusively from the bones, or whether all the organs containing this enzyme in relatively large amount (kidney, intestinal mucosa, liver) contribute a share. Though there is little doubt that the large increase of serum phosphatase in bone disease must be of osseous origin, and that the increase found in obstructive jaundice must arise in the liver, there has hitherto been little satisfactory evidence with regard to the origin of phosphatase of normal serum.

Armstrong and Banting³ have lately made an interesting attempt to add to our knowledge by experiments in which they removed various organs of adult dogs—e.g., the small intestine, the large intestine, the kidney, the liver, or the whole of the abdominal viscera—and noted the accompanying changes in the serum phosphatase level. In no case was there a fall in this enzyme in the serum after the operations, and the investigators believe that their observations support the view that bone is normally the sole source of the serum phosphatase. It is to be remarked, however, that in the normal individual the amount of this enzyme in the serum is much smaller (probably much less than one-hundredth part) than that, say, in an equal weight of kidney tissue or intestinal mucosa, or even of pancreas or lung; and Armstrong and Banting's experimental findings do not entirely preclude the possibility that the serum phosphatase represents the sum of continual leakages, from every phosphatase-synthesising organ of the body, of some tiny fraction of its store of the enzyme. If this is so, it would be expected that after removal of the organs mentioned, increased leakage from the phosphatase-synthesising cells of the remaining organs, now abnormal in their function, might easily mask any fall which would otherwise occur in the serum enzyme. In fact, in some of the recorded experi-

¹ H. D. Kay, Donald Hunter, and many others since 1929.

³ Armstrong, A. R., and Banting, Sir F.: *Canad. Med. Assoc. Jour.*, 1935, xxxiii., 243.

¹ *Arch. Neurol. and Psychiat.*, September, 1935, p. 587.

ments, as might be anticipated on this hypothesis, a fairly large post-operative rise was observed in the serum phosphatase, a rise which was sometimes persistent to the end of the experiment. If Armstrong and Banting's views of the origin of serum phosphatase are correct, the logical corollary would be to ascribe this increase entirely to increased osseous disturbance. But is this really the case? And is the available evidence really sufficient to allow us to limit the origin of the serum enzyme in a normal animal to any one organ or tissue?

AMBULANCE AEROPLANES IN NORTH AFRICA

THE French ambulance air service in North Africa has lately been described by Colonel M. J. A. Schickel.¹ In 1934 the number of patients evacuated was only 227, compared with 576 in 1933, but there was not a single accident. The Army still supplies most of the patients, but there is an increasing proportion of civilian surgical cases requiring transport by air, and the ambulance aeroplane proves increasingly popular for medical cases. Last year the average length of an evacuation flight was 285 kilometres, and flights of 1000 kilometres and more were by no means exceptional. The question of cost is engaging the attention of the authorities, who hope to effect an appreciable reduction in the charges to civilians by the exploitation of civilian aeroplanes fitted so as to take patients in an emergency. The civil population of North Africa looks to the air ambulance service more and more for help in time of need.

THE CENSUS

WITH the issue early this year of the General Tables, comprising statistics of population, institutions, ages and marital conditions, birthplace and nationality, and of the Welsh language, the normal series of publications presenting statistics derived from the 1931 Census may be regarded as complete. As originally planned and announced two types of volumes have been issued—namely, those affording for each separate county (or in a few cases a group of small counties) the statistics relating to subjects which possess distinct local interest, and those presenting for the country as a whole the statistics relating to a single subject—e.g., occupations or industries. These volumes record the different aspects of the population of 1931 in the administrative areas as constituted at that date. As a result, however, of county reviews and rearrangements under the Local Government Act of 1929 a very large number of boundary alterations have been, and are continuing to be, made. With the completion of each county reorganisation, therefore, the more important census statistics in respect of the revised areal divisions are being issued in a special supplementary series of publications—County Volumes, Part II.—a procedure especially desirable in view of the decision not to take a census next year. The population given for these newly constituted areas is, of course, that present in them on the night of April 26th, 1931, but this at least affords some basis for estimations of the present population and the double classifications give continuity with the past and future. The magnitude of the changes involved in a large county is shown in the volume just issued, that for Lancashire.² The administrative county as a whole has obtained a net increase of 1378 acres and 70 population in marginal boundary

adjustments with Cheshire and Cumberland, but has lost a net amount of 14,137 acres and 15,304 population to nine of its county boroughs. Four urban districts have been abolished and no fewer than forty-four have undergone alteration. Four rural districts have likewise been abolished and eleven others have undergone alteration. As at present constituted this volume shows that the population of Lancashire was, in 1931, roughly 5,040,000, of which nearly one-third was resident in Liverpool and Manchester.

ALUMINIUM IN FOOD

Dr. G. W. Monier-Williams, writing from the foods laboratory of the Ministry of Health,¹ summarises what is known about the effect of aluminium on the animal system, and contributes some useful experiments of his own. He points out that in fertile soils, aluminium, like iron and manganese, appears to be present almost wholly in insoluble form and that the soluble salts of these metals, especially of aluminium, make acid soils toxic to many plants. Since iron and manganese—and in some cases aluminium—are found in plants, they must reach their tissues in a soluble form via the soil water. Nevertheless aluminium does not appear to be a general constituent of plants, although in some it is found in appreciable or even considerable amounts, mostly in hydrophilic ones. It seems certain that in many cases aluminium found in roots has been left as a result of imperfect cleansing when preparing for analysis—a possibility which will be appreciated by anyone who has made analyses of root-ashes. Monier-Williams concludes that the aluminium consumed in properly cleaned vegetable food does not amount to more than 5 to 10 parts per million, but whether this small proportion is proper to the tissues or is contained in residual aluminium silicates from soil or dust it is as yet impossible to say. In animal tissues the highest proportion found—viz., 124 parts per million—was by Underhill and Peterman in the thyroids of pigs and rats, but their findings have been contested. Myers and his co-workers found only 1-2 parts in all organs, and other workers on the whole confirm the lower figures. In his discussion of analytical technique, Monier-Williams suggests that non-specific methods may have been responsible for some of the higher results.

The outcry however has not been directed against aluminium naturally present in foodstuffs, but against its introduction from vessels in which food is prepared. The action of food on aluminium vessels is, in general, slight. Monier-Williams found that whilst distilled water boiled in aluminium vessels and allowed to stand overnight contained no aluminium, tap water similarly treated took up from 7.7 to 19.2 parts per million. Dilute organic acids take up more than water, but the action of acids in foods seems to be retarded by the presence of colloids. Mutton broth with mixed vegetables, when cooked in an enamelled pan, contained 1.3 parts per million of aluminium, while a similar mixture in an aluminium pan contained immediately after cooking 7.0 parts; when kept in the same pan and reheated, after 24 hours, 10.6 parts, after 48 hours, 11.5 parts (he does not say what other metals were taken up from the enamelled vessel). The action of alkalis is well known; sodium carbonate should not be used for cleaning aluminium vessels unless it contains a small proportion of sodium silicate.

² Census of England and Wales, 1931. County of Lancaster. Part II. H.M. Stationery Office. 2s.

¹ Reports on Public Health and Medical Subjects. Aluminium in Food. By G. W. Monier-Williams, Ph.D., F.I.C. H.M. Stationery Office. 9d.

What happens to aluminium ingested with food? Since traces are found in most organs it is almost certain that some finds its way into the blood, though having regard to the ease with which it forms lakes and dilute solutions become sols, the amounts diffusing through the walls of the alimentary tract must be very small. It is not found, except in traces, in urine; what reaches the blood must therefore be removed via the intestinal secretions or bile, probably in the faeces as phosphate. It would seem likely, Monier-Williams suggests, that the diffusibility of aluminium salts into the blood through the wall of the digestive tract may vary appreciably with circumstances and with the nature of the stomach contents. Colloidal aluminium hydroxide has been administered internally as an antacid in doses of about a gramme; it is stated to be useful in peptic ulceration. Feeding experiments on animals, which received amounts very large in relation to the body-weight, showed but little action on the system, except possibly in young animals. But it should be borne in mind that the 2 mg. given to the rat as daily dose is equivalent to about 0.6 g. for a man. After discussing the clinical data Monier-Williams concludes that there is no convincing evidence that aluminium, in the amounts in which it is likely to be consumed as a result of using aluminium vessels, has a harmful effect upon the ordinary consumer. There may be individuals who are susceptible to even such small doses of aluminium as may be derived from aluminium vessels, but evidence of this is inconclusive.

THE JOURNALISTIC BLASTOMA

For his Schorstein lecture at the London Hospital on Oct. 17th Prof. William Bulloch chose the subject of Medical Periodical Literature and he asked his hearers to coöperate in stopping what he described as a malignant overgrowth. He supported the simile by an ominous picture of the shelves of the British Museum, already 60 miles in length, increasing relentlessly by a mile a year. All this fertility of expression took origin in the growth and multiplication of universities, followed by the invention of printing, and Dr. Bulloch was able to say with pride that at the end of the sixteenth century there were three universities in Aberdeenshire alone—one in Fraserburgh and two in Aberdeen—at a time when there were only two in the whole of England. But after this burst of patriotism he soon found himself once more in a mass of depressing statistics. In 1881, he said, Billings had estimated the number of doctors in the world at 180,000; to-day there were 57,000 in Great Britain alone and probably 400,000 or 500,000 all told. The World List of Scientific Periodicals, published in 1934, contains the names of 23,838 for the period 1900–31, of which Dr. Bulloch estimated that no less than 5000 are medical. Many of these were indispensable, many mediocre, and many valueless; one and all they made the task of the reader daily more arduous and more hopeless. It had been said that soon libraries would become cities and those of the population not actually writing would be engaged in cataloguing. Robert Fletcher, a London Hospital man who subsequently became Billings's chief assistant and successor at the Surgeon-General's Library in Washington, had remarked that the whole world was a conspiracy against medical bibliographers. The Index Catalogue of that Library was the greatest bibliographic work ever accomplished, and with the Index Medicus and the Quarterly Cumulative Medical Index now issued jointly with the American Medical Association, it is a storehouse

of accurate information to which we all owe an immense debt of gratitude. But the 45,600 pages of the catalogue make alarming reading. In 1893 it contained the names of 7000 books or articles on syphilis: in the period 1893–1912 14,000 more were added, and in 1913–32 another 21,000. There were no less than 116 devoted to quadruplets, and between 1913 and 1932 a total of 1280 papers on tonsillectomy made their appearance. As for tuberculosis, he had calculated that between 1893 and 1932 at least 34,000 articles and books were published on this disease—850 a year, or more than two a day for 40 years! There are 31 periodicals in circulation dealing with tuberculosis alone. "If all this information were good and true," said the lecturer, "it would be idle to increase it"; but in fact there was not a single subject in medicine that could not be enriched by the humblest member of the profession. So he did not discourage the reporting of cases or observations. Medical writing however must be approached with serious purpose, and the writer should try to see how his views compare with those already on record—a purpose for which the Index Medicus is invaluable. Thus for the reform and reconstruction of medical journals which he demanded Prof. Bulloch seemed to pin his faith chiefly (but perhaps too optimistically) to the personal virtue of their contributors: they must eschew duplicate publication and verify their references and quotations from original sources. He also hopes for an extension of critical reviews which will show what is worth reading and what is not. But it must be admitted that—in the manner of pathologists—he seemed rather more intested in the morbid appearances of his blastoma than in its treatment. We are left with the hope that by the time every second medical man edits (and writes) a journal of his own the whole structure will break down through lack of nutrition.

SETTLEMENT OF THE LLANELLY DISPUTE

It will be a satisfaction to all who care for the good name of medicine in South Wales to learn that the long drawn-out dispute between the doctors serving the Llanelly area and the workmen's medical committee has now been settled. And not settled grudgingly, but with a declaration on both sides of goodwill and coöperation which should enable the new medical service in the New Year 1936 to be a model for similar services throughout the country. The terms of the agreement were set out in the supplement to the *British Medical Journal* last week. Every practitioner in the area who is entitled to be on the insurance committee's list may join the service. There are to be no whole-time appointments, and free choice is open both to doctor and patient, remuneration to be based on the rate which existed before the dispute occurred. Besides the general practitioner service the aim is to set up a complete consultative and specialist service, the one to be paid out of the practitioners' fund, the other out of a separate fund on a sessional, or payment for service, basis. Any local management committee is however at liberty to appoint consultants on a part-time salaried basis which bears some relation to this. Each management committee is to consist of representatives of the subscribing workmen and of the practitioners, seven of each, with an agreed independent chairman, and there is to be a similarly constituted central committee to which questions in dispute may be referred. It only remains to congratulate those whose statesmanship and forbearance have rendered such an agreement possible.

MEDICAL SERVICES IN THE ABYSSINIAN WAR

Senatore Aldo Castellani, now chief consulting physician to the Italian forces in East Africa, has made a statement, reproduced in the *Policlínico* of Oct. 14th, that the health of the troops and of the Italian workmen in East Africa is excellent. In the lower lying regions of Eritrea and in some parts of Somaliland there have been cases of malaria, dysentery, and heat-stroke, but these, he says, are few in number and not as a rule severe. This state of things he ascribes largely to the fact that no doctor is mobilised for service in the colonies until he has attended an intensive course in the Clinic for Tropical and Sub-tropical Diseases which Signor Mussolini founded in Rome three years ago. All the soldiers and workmen have been vaccinated against small-pox and inoculated for typhoid and paratyphoid A and B. Inoculation against cholera has now been started as a precautionary measure, though hitherto, it is stated, there has been no case of this disease along the coast of the Red Sea. The workmen, as well as the soldiers, are provided with helmets to protect them from sunstroke, and also cholera belts. *L'Azione Coloniale* gives the number of deaths among the Italian workmen (number unstated) employed in Eritrea during the four months, April 27th to August 28th, as 141, of which heat-stroke accounts for 84, cerebro-spinal fever for 9, and malaria for 6. Sixty of the cases of heat-stroke occurred in Massowah, where the moist heat in the summer months is described as suffocating, and work was not permitted between 10 A.M. and 5 P.M.

The *Siècle Medical* of Sept. 15th published an interview with the chief of the Army Medical Corps in Eritrea, describing the organisation for dealing with sick and wounded. Each battalion is provided with mules or camels to evacuate casualties to the nearest ambulance section. From here they go by motor ambulance, if there is a road, to the divisional ambulance, where there is a surgical unit. Behind the divisional ambulances are semi-mobile formations for the treatment of wounded who cannot be moved further back. On the sea coast, at Massowah, are hospitals for the sick and wounded awaiting repatriation, and at Asmara are groups of hospitals of which the surgical hospital contains 500 beds for the lightly wounded, 300 beds for more serious surgical cases, and 200 beds for eyes, ears, and throats. In all, provision has been made for 15,000 to 18,000 sick and wounded. The prophylactic use of quinine has been made obligatory for all men in camps below 1000 metres; it is given in 1-gramme doses on two consecutive days in the week. Chlorinisation of water is secured by the use of Sterhydrol, which is issued to all the hospitals.

On the Abyssinian side few arrangements have been made for the treatment of sick and wounded—apart from the efforts of medical missionaries and others who remain in the country. Response to the appeals made by the British Ambulance Service in Ethiopia has not yet been sufficient to allow of its full relief scheme being carried out, but a small advance unit is to leave shortly and will be reinforced as soon as public support suffices. At a meeting with the British Red Cross Society last week it was agreed that the executive of the British Ambulance Service in Ethiopia, which has been recognised by the International Red Cross Committee at Geneva as an integral part of the Ethiopian Red Cross, should remain responsible for the organisation and dispatch of relief to the Abyssinian war zone. To ensure coöperation of the two funds three members of the British Red Cross Society, including the director-

general, Lieut.-General Sir Harold Fawcus, were coöpted to the executive committee of the British Ambulance Service in Ethiopia. An urgent appeal is made for the necessary funds, and donations may be sent to Sir Arthur Stanley of the British Red Cross Society, or to A. W. Tuke, hon. treasurer of the British Ambulance Service in Ethiopia, at Barclay's Bank, 54, Lombard-street, London, E.C.2.

TESTS FOR PURITY OF OXYGEN

PRACTITIONERS using oxygen in treatment need to be certain that it is pure. The tests given in the British Pharmacopœia are not very full, and in the *Analyst* for September Mr. R. F. Frederick usefully calls attention to better methods of examination. He makes a test, which is roughly quantitative, for carbon monoxide—a most undesirable impurity—by means of a proprietary reagent called Hoolamite, which is a mixture of pumice, iodine pentoxide, and fuming sulphuric acid producing a well-defined colour change, roughly proportional to the concentration of monoxide. This is claimed to be sensitive to 0.005 per cent. of carbon monoxide but does not seem to be trustworthy below 0.06 per cent. Mr. Frederick is primarily concerned with the determination of the oxygen content, for which the B.P. test is not very satisfactory, since it is based on absorption with pyrogallol in alkaline solution; and this is liable to yield carbon monoxide especially when the gas examined is, as in this case, rich in oxygen. A reagent he considers preferable is metallic copper in contact with ammonia, recommended by Hempel in 1892, and he describes a simple apparatus for the determination. In using this it must be remembered that in mixtures of oxygen and carbon dioxide the amount of the latter gas must be determined separately and deducted from the total amount absorbed by the copper reagent.

THE scheme for establishing a joint hospitals advisory board in Manchester was approved on Oct. 16th by the University council. The representatives appointed by the University are Sir Christopher Needham, chairman of council; Prof. J. S. B. Stopford, vice-chancellor; Prof. A. Ramsbottom, Prof. W. Fletcher Shaw, and Prof. E. D. Telford.

THE Buckston Browne dinner will be held in the library of the Royal College of Surgeons of England on Thursday, Nov. 14th, at 7.45 for 8 p.m. This annual dinner, at which at least half the invited guests are members of the College, has been held regularly since 1928, those present usually numbering about a hundred. After dinner there will be an exhibition of scientific and other films in the lecture theatre, and the museum will be open for inspection.

POST-GRADUATE COURSE AT BELFAST.—At the request of the Ministry of Labour for Northern Ireland, the third annual post-graduate course in medicine and surgery for panel practitioners was held during the second half of September at the Belfast medical school (the Queen's University acting in conjunction with the Royal Victoria and Mater Infirmorum Hospitals). It was attended by 25 practitioners. The morning sessions were devoted to the clinical examination of patients, and to discussions on diagnosis and treatment; in the afternoons there were lectures dealing with the more theoretical aspects of medicine, surgery, and the specialties, and with special problems arising in health insurance practice. It is proposed next year to open a limited number of places at this course to general practitioners other than those nominated by the Ministry of Labour.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LXXIV.—THE PROGNOSIS OF TETANUS

AN accurate prognosis in tetanus must be based on knowledge of the march of symptoms and signs in infections of different degrees of severity.

GRADES OF INFECTION

For convenience cases may be divided into four grades:—

1. Cases in which there is local tetanus only. This usually occurs when tetanus develops after a prophylactic injection of antitoxin. The incubation period is usually very long and the prognosis is good.

2. Cases in which there is generalised tonic rigidity only, involving particularly the masseters, the muscles of the spine, chest, and abdomen, and to a lesser extent the limbs. The incubation period is usually long, over 14 days, and the prognosis good. The tonic rigidity comes on gradually and then gradually passes off again. Reflex excitability is slight and reflex spasms do not occur. The whole process may last from one to four weeks and sometimes longer.

3. Cases in which the tonic rigidity described passes into the stage of reflex spasms. The reflex excitability gradually increases. At first manipulation of a limb merely increases its tone, but later the slightest movement of the bed-clothes throws the whole body into sudden violent contraction with opisthotonus which lasts from a few seconds to ten minutes. Such spasms occur with regularity. In patients who recover this state of reflex excitability lasts from a few days to a fortnight, at first becoming gradually more severe and then passing off. The reflex spasms stop and the tonic rigidity gradually subsides.

4. Cases in which the reflex spasms come on rapidly, sometimes within twenty-four hours of the first symptom, become rapidly more frequent and prolonged until they are almost continuous, and death, often preceded by hyperpyrexia, takes place from cardiac or respiratory failure.

In cephalic tetanus, which usually follows wounds of the head and neck, the course of the disease is less clearly defined. Convulsions and cranial nerve palsies may occur early and the muscles of deglutition and speech are more commonly affected.

HOW THE TOXIN ACTS

The symptoms of tetanus are due to the effect of tetanus toxin upon the cells of the central nervous system. Animal experiments by H. Meyer and F. Ransom (see *THE LANCET*, 1917, ii., 928) with injected toxin suggest that it passes up the axis cylinders of the motor nerves to the anterior horn cells in the brain and spinal cord. The experiments showed that the severity of the symptoms depends on the amount of toxin injected. With only a very small amount the motor cells of the limb injected are alone affected and local tetanus occurs. With larger amounts, toxin reaches the blood stream via the lymphatics, and passes up the motor nerves all over the body, so that the motor cells are affected generally and there is generalised tonic rigidity. In the nerve-cells a small amount of toxin sets up a condition of over-excitability, so that the reflex impulses which maintain the normal muscular tone become more effective and the tone of the muscles concerned is increased. If the dose has been somewhat larger its action extends to the receptor cells in the reflex arc in

immediate connexion with the affected motor cells. With still larger doses more and more motor cells and more and more reflex apparatus in the cord become affected, and there is a general increase of reflex excitability.

In human tetanus, toxin is produced in the wound, and usually the more severe the wound the worse the prognosis. Penetrating wounds and secondarily infected wounds favour the development of *B. tetani* and the production of toxin, but tetanus frequently follows quite superficial wounds which, though dirty, have been allowed to scab over, so forming septic cavities in which anaerobes may flourish. Septic blisters also form cavities in which anaerobes may grow. The prognosis is usually better in superficial wounds of the latter type, because they can be completely cleaned, than in deep extensive or penetrating wounds which are difficult to drain properly or to excise completely. Wounds of the head and neck are particularly dangerous as cephalic tetanus may follow.

Death is caused by asphyxia due to prolonged spasm of the diaphragm and respiratory muscles, or by exhaustion and cardiac failure, with hyperpyrexia as a contributory cause.

GENERAL HEALTH AND AGE

The general health and physique of the patient is a very important consideration in prognosis. An attack entails prolonged involuntary physical exertion under conditions of severe suffering and general toxæmia. Any intercurrent disease or weakness must lessen the chances of recovery. For this reason the prognosis is bad in the aged, particularly on account of cardiovascular degeneration and chronic bronchitis and emphysema. It is also bad in infants and very young children.

INCUBATION PERIOD

It is well known that the severity of a case of tetanus is inversely proportional to the length of the incubation period. This period is of great prognostic value and it can usually be measured accurately, although there is always the fallacy that a wound may not have been infected with tetanus when it was incurred but that infection supervened later. Cases with a long incubation period of many weeks or months have usually followed a prophylactic injection of antitoxin. Such patients often have local tetanus and prolonged tonic rigidity is the most marked clinical feature. The prognosis is good and many would recover without treatment. As the incubation period becomes shorter reflex excitability and spasms become a more marked feature. With an incubation period of ten days or less the case is usually severe and the chances of recovery grow less. In my own series of 18 consecutive cases under 50 treated with one large dose of antitoxin on admission, all patients with an incubation period of seven days or longer recovered and only one with an incubation period of less than seven lived. The exception had an incubation period of five days. Other published series of cases show that it is rare for patients with incubation periods of less than seven days to recover and that under five days recovery hardly ever takes place.

"PERIOD OF ONSET"

A second measurement of value in assessing prognosis is the time from the occurrence of the first symptom,

usually stiffness of the jaw, to the appearance of the first generalised reflex spasms. For convenience this may be termed the "period of onset." In very chronic cases with a long incubation period, reflex spasms may not occur at all or only begin a week or ten days after the first symptom. In most cases the shorter the incubation period the shorter the period of onset. In my own series, patients with a period of onset of three days or longer recovered with one exception (three days). Two with periods of two days recovered but the others with two days or less died. In general it may be said that a period of onset of less than two days gives little hope of recovery; with three days there is a good chance and that the outlook improves as this period is lengthened.

The combined incubation period and period of onset are also worth noting. Usually they are proportional, a short incubation period being followed by a short period of onset and vice versa, but occasionally variations occur. In general a combined period of eight days or less means a bad prognosis, and with any figure larger than this the chances improve.

OTHER FACTORS

The length of the incubation period and period of onset are probably proportional to the amount of toxin reaching the nervous system. The figures given here are approximate only and apply particularly to cases in which further absorption of toxin from the wound is prevented during the first few days by a large intravenous dose of antitoxin, say 200,000 international units, and thorough treatment of the wound.

Another factor which has an important bearing on prognosis is the severity of the reflex spasms. When these are very severe and prolonged there is a danger of death from asphyxia during a spasm unless they are controlled. The prognosis is also worse in cases with early involvement of the muscles of deglutition or very severe trismus, as these make feeding difficult.

INFLUENCE OF TREATMENT ON PROGNOSIS

Tetanus is such a variable disease that the effect of treatment in any individual case is difficult to estimate. Death is brought about in several ways when a lethal dose of toxin has reached the central nervous system. The first aim of treatment is to prevent further absorption of toxin at the earliest possible moment after the diagnosis is made. This is done by giving a large dose of antitoxin followed by thorough treatment or excision of the wound. The second aim is to control the reflex spasms due to the already absorbed toxin, so that exhaustion is prevented and the danger of death from asphyxia minimised, and also to relieve pain and to promote sleep. The third is to maintain strength by giving plenty of fluids and nourishment. I have found Avertin of more use than any other sedative in controlling reflex spasms and lessening tonic rigidity of the masseters. By its use exhaustion is prevented and feeding made very much easier. Used early in repeated doses as large or larger than those used for basal anaesthesia, it has undoubtedly been the factor which has saved some patients. There can be no doubt that the earlier thorough treatment on these lines can be begun the better the outlook. Many cases are probably lost because there is unnecessary delay in making the diagnosis, and because even when it is made treatment is not sufficiently speedy or vigorous.

SUMMARY

Prognosis in tetanus depends on a consideration of the following points: the general health, physique,

and age of the patient, the severity and treatability of the wound, the length of the incubation period, the length of the "period of onset," the ability to take nourishment, the severity of the spasms, and the speed and vigour with which treatment is begun after the symptoms have appeared.

In previously healthy patients between the ages of 2 and 50, with wounds that can be thoroughly treated and an incubation period of seven days or longer, the recovery rate should be 80 per cent. or more if thorough treatment is given within thirty-six hours of the onset. With shorter incubation periods the prognosis gets rapidly worse, and when it is less than five days almost every patient will die whatever treatment is given.

LESLIE COLE, M.D., F.R.C.P.,

Physician to Addenbrooke's Hospital, Cambridge.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

ROYAL NAVAL VOLUNTEER RESERVE

E. M. Buzzard entered as Proby. Surg. Lt. Surg. Lt. A. R. Hunt placed on the Retd. List. Proby. Surg. Sub-Lt. J. K. Sargentson to *Victory* for R.N. Hospital, Haslar, for training.

The following have been appointed Admiralty Surgeons and Agents: Mr. E. A. Saunders for Pembroke Dock, and Mr. J. Campbell for Southport.

ARMY MEDICAL SERVICES

Maj.-Gen. D. S. Skelton, D.S.O. (late R.A.M.C.), V.H.S., is appointed Hon. Surg. to the King, vice Maj.-Gen. J. W. West, C.B., C.M.G., C.B.E. (late R.A.M.C.), ret. pay.

ARMY DENTAL CORPS

Maj. N. H. Medhurst and Capt. R. G. Law retire receiving a gratuity.

ROYAL ARMY MEDICAL CORPS

TERRITORIAL ARMY

Maj. W. L. M. Gabriel to be Lt.-Col. and to comd. the 149th (Northumbrian) Fd. Amb., vice Lt.-Col. and Bt.-Col. J. A. Stenhouse, T.D., vacated.

Maj. J. D. Hart, M.C., having attained the age limit retires and retains his rank, with permission to wear the prescribed uniform.

Capt. A. D. Forgie resigns his commn.

Lt. J. L. Warner, late R.F.A. (Spec. Res.), to be Lt.

REGULAR ARMY RESERVE OF OFFICERS

Maj. C. J. H. Sharp, M.C., resigns his commn. and retains the rank of Maj.

TERRITORIAL ARMY RESERVE OF OFFICERS

Lt.-Col. and Bt.-Col. J. A. Stenhouse, T.D., from Active List, to be Lt.-Col. and Bt.-Col.

2nd Lt. E. F. Baines, from T.A. Res. of Off. (73rd (Northumbrian) Fd. Bde.), to be Lt.

SUPPLEMENTARY RESERVE OF OFFICERS

Lt. W. H. H. J. de Wyt, from Supp. Res. of Off., R.A., to be Lt., and W. H. Young to be Lt.

ROYAL AIR FORCE

Flying Offrs. G. H. Stuart to R.A.F. Station, Singapore, and R. A. Cumming to Medical Training Depot, Halton, on appointment to a short-service commission.

Dental Branch.—Flying Offr. D. P. Boyle to No. 1 School of Technical Training (Apprentices), Halton.

RESERVE OF AIR FORCE OFFICERS

D. F. E. Nash is granted a commission as Flying Offr. in Class DD.

INDIAN MEDICAL SERVICE

Capt. T. R. R. Pai, M.B., relinquishes his temp. commn. *Indian Medical Department.*—Capt. (Sen. Asst. Surg.) L. A. Francis to be Maj. (Sen. Asst. Surg.).

POST-GRADUATE LECTURES

For the fourth week in succession we publish summaries of lectures delivered to post-graduates at recent week-end courses in the London teaching schools. Prof. Browne's was delivered at University College Hospital and Dr. Livingstone's at King's College Hospital.

THE TREATMENT OF PLACENTA PRÆVIA

(PROF. F. J. BROWNE)

BEFORE dealing with methods of treatment it will be useful to lay down some general guiding principles.

1. Mortality from placenta prævia is much higher in domiciliary than in institutional practice. This is chiefly because only in the latter are proper facilities available for treatment.

2. Delay in treatment greatly diminishes the chances of success.

3. As hæmorrhage is the most frequent cause of maternal death every effort should be made to prevent loss of blood before, during, and after delivery.

4. As sepsis is the second most important cause of death all necessary examinations and manipulations should be carried out with the most strict attention to surgical asepsis and antiseptics.

If ante-partum hæmorrhage, however slight, occurs the patient should be removed at once to a hospital or some similar institution. The Departmental Committee on Maternal Mortality in its final report recognised this necessity, and recommended that the first onset of "warning hæmorrhage" should be the signal for removal to a hospital or an institution offering equal facilities. Before removal no internal examination should be made, for the cervix is usually so high up that it is impossible to get a finger through the internal os unless the patient is under a general anæsthetic and the whole hand in the vagina. Besides, internal examination may cause severe bleeding with which it is difficult to deal effectively in the patient's home. Neither should the vagina be packed before the patient is removed because, in the first place, it is impossible to pack properly unless the patient is under general anæsthesia; because, secondly, the insertion of a vaginal pack practically precludes Cæsarean section, should this be later considered advisable; and because, thirdly, it is doubtful whether the pack really controls hæmorrhage.

Before removal a hypodermic injection of morphia should be given and a tight abdominal binder applied together with a sterile vulval pad and perineal bandage. The binder should come well up over the fundus so as to press, as far as possible, the presenting part downwards on to the low-lying placenta. On arrival the patient should be blood-grouped, and the question then arises whether treatment is to be active or expectant.

EXPECTANT TREATMENT

Expectant treatment (rest in bed and sedatives) is indicated when the bleeding is slight and provided the patient can be kept under constant observation and that someone who is competent to deal with the case is living on the premises or near enough to reach the patient in ten minutes. The nurse in charge should be warned to send at once should bleeding start. If expectant treatment is being carried out a vaginal examination is unnecessary, and is indeed inadvisable. If, however, bleeding is severe, or continues in spite of rest, or if it recurs

more than twice or thrice, resort should be had to active treatment.

ACTIVE TREATMENT

When it is decided that the case is one for active treatment it is necessary first of all to find out the exact state of matters by internal examination. For this purpose the examination should not be carried out on the patient's bed in the ward but only in the labour room or operating theatre with all preparations made to deal with bleeding should this be alarming, as it is apt to be after introducing the finger through the internal os. The patient should be grouped if this has not already been done, preparations should be made for blood transfusion, and if the patient has already lost severely a blood donor should have arrived at the hospital. In such cases, too, especially if the patient is not in labour, it is usually a wise precaution to have all preparations made for Cæsarean section so that if this is considered best it may be proceeded with after the least possible delay.

In carrying out this vaginal examination, a general anæsthetic should be given and the whole hand introduced into the vagina. To facilitate this it is a good plan to "iron out" the vagina by the method of Potter. With the patient in the lithotomy position, and the external genitals having been shaved and rendered surgically clean, one or two ounces of ether soap are poured into the vagina. One or two fingers are then passed up to the posterior fornix or as near to it as possible and the posterior vaginal wall ironed out by bringing the finger firmly downwards in contact with it as far as the vulva. Three, four, and five fingers are successively introduced and similarly used until finally it is possible to insert the whole hand easily and pass a finger through the internal os, and explore the situation of the placenta. Care should be taken to separate it as little as possible, so as to save unnecessary blood loss.

Now what are the methods of active treatment available? It should not be forgotten that many cases of placenta prævia (10-15 per cent.) need no treatment at all. These are chiefly those in which the bleeding is slight, and the placenta dips but slightly into the lower uterine segment. When labour starts and the membranes rupture the presenting part descends and pressing on the placenta, prevents all further hæmorrhage.

Rupture of the membranes, followed by the application of a tight binder, is an excellent method of treatment if hæmorrhage is comparatively slight and labour pains are present and the os dilating, and the placenta does not extend beyond the margin of the internal os. Both the maternal and foetal mortality are exceedingly low, chiefly because the method is used only in the milder cases.

Willet's forceps.—The use of this instrument should be confined to cases of partial placenta prævia. The membranes must of course be ruptured before applying the forceps and the head should be fixed by an assistant pressing it down as far as possible into the pelvic brim. A weight of 1½ lb. should be attached to the handles. The forceps give less complete control of the bleeding than podalic version and extraction of a foot, especially as they are sometimes difficult to apply and may easily slip off after a time, but they have the great advantage that they can be applied when the os only admits a finger. The foetal mortality too is lower than after podalic version, as the risks attendant on breech delivery are obviated.

Podalic version followed by extraction of a foot.—The podalic version may be carried out either by external manipulation alone—perhaps the method most commonly used nowadays, especially if the child is premature—or by the bipolar method of Braxton Hicks, or, if the os is half dilated, by introducing the whole hand into the uterus and seizing and bringing down a foot. Before a foot can be extracted the os must admit at least two fingers. A weight of 2 lb. is attached to the foot by means of a gauze strip and allowed to hang over the foot of the bed, but as continuous pressure is thus exerted on the placenta the outlook for the child is improved if a gauze strip is simply attached to the foot and an assistant instructed to make traction on this should bleeding start. Delivery should always be allowed to occur spontaneously and slowly, and the interval used to promote the patient's recovery from shock and the effects of blood loss, it may be by blood transfusion.

Of all the conservative methods used in treatment of placenta prævia this gives the best control of bleeding, and in skilled hands the results as far as the mother is concerned are excellent. How good they may be is illustrated by the record of Stratz who in 110 cases treated by bipolar version, and all by himself, had a maternal mortality of only 0.9 per cent. (one death from pulmonary embolism), though the foetal mortality was 64 per cent. Podalic version must therefore be still regarded as the standard method of treatment.

Vaginal pack usually followed by some other manipulation such as bipolar version.—This method is much used when the os does not admit a finger, the bleeding is severe, and the patient not in labour. The best packing material is sterile pledgets of cotton-wool that have been soaked in lysol solution and then squeezed dry. They are, however, difficult to remove without injuring the vaginal mucous membrane, and a sterile gauze roll is a good substitute. The gauze should be similarly treated—viz., soaked in lysol and then squeezed as dry as possible. The pack must be inserted under general anaesthesia, and it is necessary to lay a good foundation by packing the fornices firmly to start with so that the cervix is surrounded by a firm collar. On this firm foundation the remainder of the pack is inserted and driven well home so that it distends the vagina tightly as far as the vulva. The operation is completed by the application of a tight abdominal binder coming well up over the fundus, a vulval pad and perineal bandage attached to the binder in front and behind.

At best the vaginal pack is a septic appliance, and blood clots gather behind it and form an ideal culture medium. At the same time as a means of controlling hæmorrhage it is unreliable and not infrequently, even after the most painstaking insertion, the pack is found to be soaked through with blood. Neither can it be relied on as a means of inducing uterine contractions—thus causing dilatation of the os—the second advantage that is claimed for the pack. Finally, the insertion of the pack practically debars one from performing Cæsarean section even should that ultimately be regarded as necessary in the interests of mother or child. Statistics have shown repeatedly that the maternal mortality from sepsis is twice as high when the vagina has been packed. For all these reasons I believe that the use of the pack should be abolished or at least that it should be used only in the following combination of circumstances—a closed os, severe hæmorrhage,

and the presence of some condition such as sepsis that renders Cæsarean section inadvisable. Stratz, whose results have been previously quoted, condemns the pack and did not use it in any of his cases. The alternative when the os is closed is Cæsarean section.

Of late years *Cæsarean section* has been coming into more frequent use in placenta prævia. This is not surprising when we consider that though by conservative methods and skilled treatment the maternal mortality can be reduced to a remarkably low figure, yet the outlook for the child remains consistently bad. Even Stratz in 173 cases, though his maternal mortality was 0.6 per cent., had a foetal mortality of 44 per cent. Cæsarean section alone offers any hope of improving this. But the foetal death-rate can never be really low—probably little less than 30 per cent.—for many children are too premature to survive and others are killed by placental separation before the patient is seen.

The indications for Cæsarean section may be defined as follows:—

1. Severe hæmorrhage when the os is closed or fails to admit a finger. The alternative is the vaginal pack.
2. If the os does not admit two fingers and the placenta entirely covers it. The alternative here is Willett's forceps, but it is undesirable to apply them through the placenta.
3. Placenta prævia of any degree in an elderly primigravida, or in any woman who demands a live child, if the os is less than half dilated, and provided the fœtus is viable (over thirty-five weeks), and the patient not infected.
4. Cases complicated by disproportion or other condition likely to lead to obstructed labour.
5. Patients in extremis where it is felt that manipulations per vaginam, or even a vaginal examination, may be attended by a further severe hæmorrhage that may prove fatal.

Management of the third stage.—After the child is born the most careful watch must be kept for post-partum hæmorrhage. It cannot be too strongly emphasised that the great majority of the cases that end fatally from hæmorrhage do so because of post-partum hæmorrhage, and that even a small post-partum loss, which would after a normal labour be of no account, may be enough to turn the scale against a patient already severely depleted by ante- and intra-partum hæmorrhage. Everything should therefore be ready for the immediate and energetic treatment of post-partum bleeding—including pituitary extract, ergometrine, hot douches, sterile gauze for packing, suture needles and catgut, and donors for blood transfusion. If the medical attendant is wise he will control the fundus himself instead of leaving it to an assistant. If hæmorrhage takes place in spite of the uterus being well contracted the cervix must be exposed by a speculum and examined. If it is torn and bleeding, a continuous locked catgut suture of double No. 1 catgut should be inserted immediately. As, however, the placental site is in the lower uterine segment, which does not contract and retract well, it may bleed freely even when the uterus seems well contracted. In such cases a hot intra-uterine douche at 118° F. may be of the greatest value and above all bimanual compression. Expression of the placenta by Credé's method is unnecessary as long as there is no hæmorrhage, but should this occur it must be expressed at once. If attempts at expression fail it must be manually removed.

VALUE OF BLOOD TRANSFUSION

The prophylactic and therapeutic value of blood transfusion should be constantly kept in mind by

those who have to treat cases of placenta prævia. About 65 per cent. of the patients who die, do so because of hæmorrhage, and most of these deaths could be prevented by the employment of measures directed to the replacement of the blood lost. Its great value has been strikingly shown by Bill, who, chiefly by means of it, reduced his maternal mortality from 11 to 1·8 per cent. The proportion of his cases requiring and receiving blood transfusion was 12·4 per cent. He points out that most patients who die of post-partum hæmorrhage do so because the anæmia consequent on ante-partum bleeding produces an atonic state of the uterus, so that it is unable to contract properly after delivery. To prevent this he gives blood transfusion *before delivery* to every patient whose red cell count is below 3,000,000 and blood pressure below 90 systolic and 60 diastolic. He advises that the transfusion should be in the hands of a member of the staff who is an expert in the technique and in the blood reactions. We have already seen that the patient should be grouped on admission and that a donor should, in every serious case, be on the premises before treatment is begun. If, for any reason, blood transfusion is impossible, saline infusion will be of value.

HIGH BLOOD PRESSURE AND ITS TREATMENT

(DR. J. L. LIVINGSTONE)

THE subject of high blood pressure is a large one, and I propose to restrict my remarks to a small part of it—namely, the treatment of Allbutt's "hyperpiesia," or "essential hypertension" in which the pressure is raised primarily and apart from renal disease or other obvious causes.

In my experience it is a common thing to find that patients have been treated for high blood pressure quite unnecessarily because the pressure has not been taken properly. I would remind you that it is important to have the patient reclining on a couch for a few minutes before taking a reading. A rough reading should be taken by palpation of the radial artery, noting the level at which the pulsation returns as the pressure is released. The valve should be released completely and then the systolic and diastolic pressures noted by auscultation over the brachial artery; the systolic pressure is read at the point at which the sound is first heard, the diastolic pressure when the sound suddenly changes from a ringing to a dull muffled sound. The valve is released completely and the process repeated, until the pressures become stable; this often requires three to five readings, the last usually being the lowest. With nervous people two further examinations should be made, on separate days, before the true blood-pressure reading is considered established.

Most observers agree that a persistent reading of more than 150 mm. Hg systolic and 100 mm. diastolic may be taken as abnormal. The diastolic pressure, being an estimate of the load which the arteries have to support, and against which the heart has to work continuously, is probably of more importance than the systolic figure; it is also more constant. The pulse pressure should not exceed 60 mm. and it is a definite guide as to the cardiac output.

From the clinical side we know that in the early stages of the disease there are no symptoms; the only guide is a raised blood pressure, often of a fluctuating type, but later becoming more constantly

raised. It is only in the late stages of the condition when the arterioles, at first spasmodically contracted, are permanently narrowed by intimal thickening, that symptoms are conspicuous. The clinical classification of benign or red hypertension, with death after the sixth decade, as compared with the malignant or pale type, associated with renal damage and death before 50, is perhaps worth noting.

ÆTIOLOGY

When we consider the ætiology of hypertension we are confronted with a mass of theories, and as yet our knowledge is very incomplete. In animals there is only one method of causing a persistent rise in blood pressure—the destruction of the aortic and carotid sinus nerves (Heymans et al., *Sinus Carotidien*, 1933). In the dog the blood pressure rises to 300 mm., and there is hypertrophy of the left ventricle with interstitial fibrosis of the kidneys. In man evidence of disease of the carotid sinus, as associated with hypertension, has not been definitely proved.

Pitressin, a hormone from the posterior pituitary, definitely raises the blood pressure in animals temporarily. In man hypertension may be associated with basophil adenomata (H. Cushing, 1933), but excess of basophil cells is not found constantly in the pituitary glands of hyperpiesics. Adrenaline raises blood pressure also, in animals, and in man suprarenal chromaffin tumours have in rare cases been associated with hypertension, which has disappeared after removal of the tumour (C. H. Mayo, 1927). Recent work points to the pressor effects of the pituitary, suprarenals and thyroid, acting via the sympathetic system, and to the depressor action of the pancreas, acting on the parasympathetic or vagus system. The recently isolated pancreatic hormone, Vagotonine, seems to have important depressor effects: (1) it increases vasodilator tone while decreasing vasoconstriction; (2) it slows the heart-rate; and (3) it inhibits the action of adrenaline.

I would draw attention to the recent observations of Parkinson and Hoyle (1934) on the importance of latent hyperthyroidism in hypertension. No doubt we can all call to mind cases of hypertension exhibiting tachycardia, tremor, and loss of weight, with slight enlargement of the thyroid. In view of the recent work in America on the total ablation of the thyroid gland in cases of congestive heart failure associated with angina, this observation of Hoyle and Parkinson is of considerable importance.

From the clinician's standpoint, however, the ætiology is obscure though two facts stand out: (1) the marked familial incidence of hypertension; (2) the apparently increasing frequency of the condition, which seems to be associated with the "speeding up" of work and play in modern life. The frequency of high blood pressure may be appreciated from the fact that in the United States the mortality due to its consequences is estimated at 10 per cent. of the total mortality—a figure greater than the total death from cancer, tuberculosis, and respiratory diseases (including pneumonia) combined. Halls Dally, in his book on *High Blood Pressure* (1934), gives an estimate of 7 per cent. for this country.

The ratio of actual to expected deaths from the point of view of the life assurance societies, as given by Otto May, is shown in the following Table. These figures speak for themselves as regards the seriousness of the condition.

TREATMENT

1. *The early case.*—The patient is a young man; his symptoms are negligible; there is no evidence

of hypertrophy of the cardiovascular system, a fluctuating blood pressure being the only sign. He should be kept under observation and the blood pressure should be recorded perhaps twice a year; the actual figures should not be communicated to him, for this is apt to cause a blood-pressure phobia. Excesses of all sorts should be avoided, especially

Mortality among men and women taking out policies with the Prudential Society during the period 1920-24. The ratio of actual to expected deaths among ordinary branch policy-holders medically examined is taken as 100. (Abridged from British Medical Journal, 1925, ii., 1166.)

Systolic pressure at entry.	Mortality.
Not recorded	97.1
Under 140 mm.	102.8
140 to 170	133.6
Over 170	219.6
Over 200	827.5

as regards tobacco, alcohol, long hours of work, and late nights. Nine hours in bed on five nights a week is good advice. Causes of underlying anxiety and worry should be discussed and put right if possible. Hard physical exercise should be encouraged because it directly lowers the pressure. A course of bromide or Luminal in the highly strung type may be prescribed with benefit for some months. These simple measures are sometimes sufficient and the fluctuation in the blood pressure may become less marked as a result of them.

2. *The medium case.*—Here, let us say, there is a persistently raised blood pressure (150/95 or over), but without signs of hypertrophy of the heart or vessels and with few symptoms. In such a case the treatment must be more definite and drastic, the patient should be warned that he is on the way to becoming a hyperpietic and that he must take treatment seriously. The daily round of wear and tear must be reduced drastically; office hours should be shortened, overtime work prohibited, and a half day's golf should be taken in the middle of the week with a restful week-end. Driving a car through traffic to and from work should be avoided, the patient using a chauffeur or public forms of transport.

The diet should be restricted in rich purines, liver, kidney, shell-fish, and so forth; red meat should not be taken more than once daily; and on Friday the diet should be strictly vegetarian. In the adipose type of patient the fats, potatoes, puddings, pastries should be curtailed and the bulk of the diet should be made up by green vegetables, salads, and fruits. The weight should be recorded weekly; an hour a day should be given to walking and other exercise. A Turkish bath once in ten days is useful.

A course of iodine should be given—e.g., Lugol's Iodine Solution,

$\begin{matrix} \text{m. v.} \\ \text{m. vii.} \\ \text{m. ix.} \\ \text{m. xi.} \end{matrix} \left. \begin{matrix} \\ \\ \\ \end{matrix} \right\} \text{Night and morning for a week}$

and then m. vii. each night for six weeks.

I find it best to give the patient a dropping bottle of the solution and let him count the drops himself into a small glass of water. Small doses of thyroid to decrease weight, and with the idea of diminishing the arterial thickening, are often useful. I rarely use a bigger dose than gr. 1 daily. Sedatives should be given for sleep if necessary and nine hours should be spent in bed each night.

Septic foci should be sought for and treated. The bowels should be kept well open with a daily small dose of salts and a weekly blue pill.

If there is not much improvement after six weeks

of this régime, the patient should be put to bed for six weeks. If he had pulmonary tuberculosis, an enlarged prostate, or even an acute appendix, rest in bed would be regarded as essential. Hyperpiesia is quite as serious a condition, and this aspect of the matter should be put to the patient and will often assist in making him consent to undergo treatment in bed.

The type of case with tachycardia, nervousness, moist hands, and possibly auricular fibrillation is not uncommon, and special attention should be paid to enlargement of the thyroid. Mild grades of hyperthyroidism are probably more common than is generally suspected, and partial thyroidectomy may result in a substantial and persistent lowering of the blood pressure in these cases.

3. *Advanced cases.*—There is a persistent blood pressure of over 180/110 and signs of myocardial hypertrophy, angina of effort, and possibly retinal vascular disease; there may be evidence of early renal failure. The treatment of these patients can only be palliative but much can be done to minimise symptoms and to prolong life. It must be remembered that this class of case requires a moderate hypertension to keep up the renal circulation; there is an optimum pressure at which the symptoms are least marked; if the pressure falls much below or rises much above this level, the patients do not feel so well. The main therapeutic remedy is rest in sufficient dosage. The vasodilator drugs, as a rule quite useless in the prevention of hypertension, may have an effect on these patients and keep the blood pressure within limits.

Erythrol tetranitrate, gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$, or mannitol hexanitrate, gr. $\frac{1}{4}$ to gr. 1, six-hourly, have a more prolonged action than sodium nitrite or nitroglycerin. Headache and flushing are often troublesome with these drugs, but by careful adjustment, a suitable dose may be found. Euphylline (theophylline-etheline-diamine) grs. 1½ or theobromine grs. 5, may also be tried. Vagotonine, a pancreatic hormone, has a definite action on the arterial tone: daily injections of 0.02 g. for three weeks may cause a definite fall in pressure, which persists for some weeks (Halls Dally). If there is no marked lowering of the blood pressure after the first dose, it is probably not worth while continuing this drug. Acetylcholine 0.1 to 0.2 g. subcutaneously has a similar action, and Bayer's Padutin (Kallikrein), which may be taken by mouth in tablets containing three units, is said to have a definite effect.

The Anglo-French Drug Company have recently produced a tablet named Hypotan, which is said to contain methylacetylcholine bromide 5 mg., bromocholine bromide 5 mg., and chloral hydrate 5 cg. (gr. $\frac{1}{4}$). On theoretical grounds this should lower blood pressure. I have no practical experience of the drug however, as it has been only recently introduced.

NEW MENTAL HOSPITAL AT BRISTOL.—Bristol city council have decided to proceed with the erection of a new mental hospital at Barrow Gurney. Two years ago it was estimated that it would cost £187,000, but the increased cost of wages and materials have now brought the total to about £250,000.

MOUNT VERNON HOSPITAL, NORTHWOOD.—The heavy demands on this hospital have made it necessary to extend the X ray department. This will involve an expenditure of £10,000, and as the last couple of years' expenditure has exceeded income by over £5000, the hospital is forced to make a public appeal for funds.

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

SECTION OF PATHOLOGY AND
BACTERIOLOGY

Prof. A. MURRAY DRENNAN (Edinburgh) presided over this section, when Prof. H. A. WOODRUFF (Melbourne) opened a discussion on

Some Toxæmias of Animals due to Anaerobic Organisms

Prof. Woodruff gave a comparative account of recent work on anaerobe toxæmias in animals, and indicated the bearing of this on the toxæmia of intestinal obstruction in man, the nature of which was still controversial. The first disease discussed was "black-leg" in calves, a disease which attacked healthy young animals producing a local necrotic infection of limb muscles, due to *B. chauvæi*. Although it was not possible to cause infection experimentally by simple ingestion of cultures, ingestion was believed to be the natural route of entry of the organisms, infection by which was probably determined by some other unknown factor. Prophylactic vaccination was effective. Braxy in sheep was an infection of the abomasum or true stomach by *vibrio septique*, and an important predisposing factor appeared to be the chilling of the stomach by cold masses of food in the contiguous rumen during frosty weather. Animals surviving the first winter on a braxy farm were thereafter immune; vaccination also gave good protection. Black disease or infective necrotic hepatitis of sheep was an infection by *B. adematensis*, which was closely associated with liver fluke. Large doses of *B. adematensis* spores could be given to sheep by mouth without harm; these spores, however, could lie latent in the animal's tissues, and subsequently become active during the period of migration of the liver fluke, which thus acted as a directing factor in causing the necrotic hepatitis. Vaccination against *B. adematensis* and anti-fluke measures were effective preventives. Infectious entero-toxæmia of sheep was a disease with close resemblances to the toxæmia of paralytic ileus in man. It was caused by *B. oritozicus* which multiplied in the bowel contents, in which an absorbable highly potent toxin was produced. The resulting toxæmia was the essential feature of the disease, in which the tissues of the body were not invaded by the bacillus. Two other anaerobic organisms causing disease in sheep were *B. paludis* and the bacillus of lamb dysentery. It was of great interest to note that between *B. welchii*, *B. oritozicus*, *B. paludis*, and the bacillus of lamb dysentery close cross-toxicity relationships existed. Here was a group of bacteria with different but related toxic effects. Clearly in the investigation of anaerobic infections, proper antigenic analysis and toxin identifications were of first importance, since infections serologically different would require different serum treatment.

Prof. C. E. HERCUS (New Zealand) referred to the kinds of anaerobe infections seen in New Zealand. Tetanus had a patchy distribution there; and, although catgut infection was suspected in a number of cases, the tetanus bacillus had not been isolated from the gut. There was no record of botulinus infection in New Zealand. Clostridia infections occurred occasionally; in several cases they appeared

to have been determined by pyrogenic infections. As to anaerobe infections in animals, black leg and entero-toxæmia were present in New Zealand; but there was no braxy, and black disease was seen only in one area. Prof. Hercus doubted whether entero-toxæmia had any analogy in human pathology. He believed that nutritional factors were important in predisposing to entero-toxæmia infections.

Dr. G. H. OXER (Western Australia) agreed with the last statement. He believed that braxy existed in sporadic form in Australia. The development of active immunity was of great importance in these infections, subclinical but immunising attacks of which must be frequent. Vaccine immunisation gave good results; and there was evidence that vaccination of pregnant ewes conferred on the lambs a passive immunity to lamb dysentery which lasted for some weeks after birth.

Dr. C. W. ADEY (Melbourne) urged the necessity for distinguishing between the pseudo-toxins and true toxins of anaerobic bacteria. The pseudo-toxin of *B. welchii* would kill a mouse immediately; the true toxin caused death in 2 to 24 hours, and an important symptom was hæmoglobinuria due to the hæmolytic element which was always present in the true toxin. The hæmolytic effect was responsible for the jaundice and hæmoglobinuria in women with post-abortive *B. welchii* infections. The fact that paralytic ileus was not accompanied by signs of hæmolysis suggested that the true toxin of *B. welchii* did not play the main part in the resulting toxæmia. Dr. Adey advanced reasons for believing that entero-toxæmias might be due to the pseudo-toxins of the responsible organisms.

Dr. L. BULL (Melbourne) suggested that hæmolysis in *B. welchii* infections denoted blood stream invasion. He believed that there was no illness in man comparable with entero-toxæmia in sheep.

Prof. WOODRUFF, in reply to Prof. Hercus, said that he thought it quite possible for a pyrogenic infection to determine an anaerobe infection; and he demonstrated how, on plate cultures, the growth of an aerobe on one part of the plate could facilitate the growth of an anaerobe on another part.

Inapparent Virus Infections

This was the title of a discussion opened by Dr. F. M. BURNET (Melbourne), who said that a virus or bacterial infection might be mild and inapparent or frank and obvious. From an ecological point of view, it would be advantageous to both the host and the parasite that infections should be mild and not destructive to the host. Hence we might expect that most infections would be inapparent. This was certainly true of many virus diseases, and probably of all endemic diseases. Inapparent infections were of great importance because they were immunising. In the development of immunity there were three phases: (1) passive immunity transferred to the young from the mother and lasting for a variable period of early post-natal life; (2) active immunisation during childhood as the result of inapparent infections; (3) reinforcement of this active immunity as the result of repeated contacts with the parasite in adult life. The curves of age-incidence of typhoid, typhus, pneumonia, cerebro-spinal fever, poliomyelitis, scarlet fever, diphtheria, &c., all accorded with this conception of the development of immunity.

Dr. Burnet discussed psittacosis in some detail. He had found this disease very prevalent in many species of wild and confined Australian parrots, usually without causing any symptoms of illness in the infected birds. In other words, most of the infections were inapparent. There was a nice equilibrium established between the bird and the virus, an equilibrium which had probably been in existence for a very long period. No cases of human psittacosis had been seen in Australia. Poliomyelitis was almost certainly present in all civilised communities, mostly in inapparent immunising form. Here again there was an equilibrium between host and parasite. Outbreaks of the disease in clinically apparent form were due to the disturbances of the equilibrium by other factors which modified either the condition of the host or of the virus. Although there was no proof, Dr. Burnet thought it possible that the outbreak of X disease in Australia in 1917-18 might have been due to the virus of louping-ill.

Prof. H. K. WARD (Sydney) paid a tribute to the researches on influenza by Laidlaw, Wilson Smith, and Andrewes who were leading the way to possible control of this major epidemic disease. He commented on the nature of interactions of viruses, immune sera, and complement, reactions which are still obscure. With regard to the long duration of immunity in virus diseases, he suggested the possibility that the virus persists in the body and excites antibody formation throughout life.

Dr. BULL held that no essential differences existed between the epidemiology and the serology of virus diseases and bacterial diseases. He thought too that the concepts brought forward by Dr. Burnet should not be regarded as general "laws of nature." When a pathogenic virus had more than one host, the problem was complex, and the equilibrium between parasite and hosts would be less exact. Moreover, the effects of alcoholism, disease and habits on the incidence of virus infections in adults must be taken into account in interpreting our age-incidence curves for these infections.

Dr. E. V. KEOGH (Melbourne) considered Dr. Burnet's hypotheses reasonable and suggestive. A major difficulty in virus work was the lack of cheap satisfactory indicator animals. The use of the developing chick embryo as an indicator, devised by Dr. Burnet, was a great advance in virus research. The number of lesions developing in the chorio-allantoic membrane was an accurate measure of the intensity of the virus, and the antibody content of immune sera could be estimated by its effect in reducing the number of lesions.

Prof. HERCUS said that Dr. Burnet's remarks raised profound evolutionary problems. The New Zealand experience of poliomyelitis suggested that, following the initial introduction of the disease, there had been a gradual attainment of equilibrium between virus and host. Did the attainment of equilibrium eliminate the risk of serious epidemic outbreaks? The influence of nutritional and other environmental factors on the age-incidence curves and district distribution of virus diseases must be considered.

Dr. BURNET, in reply, agreed with Dr. Bull that the epidemiological and serological features of virus and bacterial diseases were essentially alike. With regard to immunity in virus diseases, the persistence of the virus in the host's tissues must be admitted as a possibility, but usually the permanence of the immunity was due rather to persistence of the disease not in the individual, but in the community, the

individual having his immunity constantly reinforced by intermittent contact with the parasite. In reply to Prof. Hercus, he said that the experience of other communities—e.g., in New York—showed that the attainment of general equilibrium between the poliomyelitis virus and host did not ensure against future serious outbreaks in the young.

Dr. A. BOLLIGER (Sydney) read a communication on

Determination of Hæmoglobin as Globin Picrate

The method depended on the acid-combining power of globin. The essential features were that alcoholic picric acid solution was added to the hæmoglobin solution or to the red blood-cells, the precipitate was washed with alcohol and ether, and the picric acid content was estimated by titration with methylene-blue. The estimation could also be made by titrating the residual uncombined picric acid. The results of the method agreed very closely with those of the gasometric methods of Haldane and Van Slyke. In reply to a question by Prof. Drennan regarding the sensitivity of the test, Dr. Bolliger said accurate results had been obtained with as little as 0.1 c.cm. of blood.

SECTION OF MEDICAL SOCIOLOGY

Dr. E. KAYE LE FLEMING (Wimborne) presided over this section when Dr. ALLAN VICKERS (Western Australia) opened a discussion on the

Australian Aerial Medical Services

He said that it was due almost entirely to the inspiration and tenacity of purpose of Rev. John Flynn that the Aerial Medical Service, commonly known as the "Flying Doctor" service was established. Mr. Flynn's work as superintendent of the Australian Inland Mission (the Bush department of the Presbyterian church) had, since 1912, taken him constantly into the huge sparsely settled areas of the back-country. In Australia, close settlement was confined to the eastern and southern fringes of the continent. Over the remainder, in an area larger than Western Europe, were scattered thousands of settlers, whose nearest neighbours were of the order of 100 miles distant, and whose nearest hospital and doctor were often 200 miles away. Their means of communication was primitive, perhaps a ride on horseback of 60 to 70 miles to the nearest telegraph station. Roads were often only bush tracks impassable in the wet season. It was in times of acute illness that the delay in securing medical advice, and the transport difficulties, emphasised this isolation. Mr. Flynn was responsible for the establishment of small hospitals, staffed by two trained nurses, at some of the most isolated spots; and he conceived the idea of an aerial medical service, with a central base. Such a service would have been of little use without some means whereby the outback settler could summon the doctor to his aid, and Mr. Flynn's solution of this problem was the installation of wireless apparatus. Technical difficulties were overcome by the ingenuity of the chief wireless engineer, Mr. Alfred Traeger, and financial assistance was received from many individuals and organisations, chief of which was the H. V. McKay Charitable Trust.

In May, 1928, the first aerial medical service base was established at Cloncurry (Queensland). Experimental in its inception, it soon proved its usefulness and practicability. Seven members of the medical

profession in Australia have, in succession, acted as medical officer in charge at Cloncurry for periods ranging from six months to three years. The people whom it served regarded the Aerial Medical Service not as a novel experiment, but a proven safeguard to be relied on in their hour of need. Dr. Vickers said that the central wireless station, at the Cloncurry base, employs a maximum power of 500 watts, operable on several wave-lengths. Messages outwards to small sets are sent in ordinary voice so that reception at the outposts is as easy as listening-in to a broadcasting programme. These outpost sets not only receive, but also transmit messages to the Cloncurry base. The source of power for the transmitters is a small high-tension generator driven by bicycle pedals, thus avoiding the maintenance of a complicated engine and the necessity for an unfailing source of fuel. All that is necessary is man-power. For distances up to 200 miles, communication from an outpost set to Cloncurry, or between two outpost sets, can be carried on in ordinary voice. For greater distances, it is considered advisable to use Morse, which has been made available to all by a typewriter adaptation. Dr. Vickers said that outposts were being added as funds permitted; at present there were 35, scattered over Northern and Central Australia. The most distant was over 700 miles from Cloncurry. The ambulance aeroplane was a cabin type of machine adapted to carry a full-length stretcher, with room for the doctor beside the patient. A complete battery-operated transmitting and receiving wireless set enabled the doctor to keep in touch with his base. Fuel supplies were often carried from rail-head by camel for distances up to 400 miles. Petrol costs as much as 4s. 6d. per gallon.

Dr. Vickers proceeded to outline the activities of the Aerial Medical Service; medical advice by wireless; emergency treatment, including that of major surgical catastrophes and of less serious, but disabling conditions; coöperation with other medical practitioners, and the supervision of outlying hospitals without a permanent medical staff. He stressed the fact that residents in isolated districts felt an increased sense of security in the very existence of the service. The area covered from the Cloncurry base was up to a radius of about 400 miles, an area, in fact, just a little larger than the British Isles. Occasionally, flights had been made far beyond this boundary, the longest yet made being 2500 miles, in the course of which the patient was transported 1250 miles. The value of the service to Queensland and inland Australia was inestimable. The development of the scheme was national in character. It was hoped that the development and control would remain in the hands of public-spirited individuals and organisations, with a certain measure of Government support and assistance. There had been formed an association known as Australian Aerial Medical Services, a section of which was to be established in each state, with headquarters in the capital city. It was hoped to establish bases at Port Hedland and Wyndham in the near future, and three others later on. Dr. Vickers concluded with a tribute to the memory of the late Dr. Dunbar Hooper, and expressed the hope that the various dominion services, though independently controlled, might achieve some measure of coöperation under such a title as the British Empire Aerial Medical Services, with all the prestige which that great name would confer.

Rev. JOHN FLYNN (Sydney), after an expression of appreciation of the interest manifested in the scheme, spoke of the immeasurable loneliness of

the Australian central desert lands. The railways radiated centrally from the coast, but stopped far short of the central lands. The cities were with minor exceptions all coastal. The rainfall of the northern parts of Australia was quite good, and the land was therefore habitable. In indicating the situation of the 35 outposts mentioned by Dr. Vickers, Mr. Flynn showed that one-half were in settled areas of the continent. Plans had been formulated for the ultimate endowment of 500 such outposts. He emphasised the coördination necessary for any such scheme, the necessity for a national conception of the scheme, under one control, the ideal of a British Empire aerial medical service, and the desirability of establishing a travelling scholarship for doctors as a means of spreading ideas and of promoting understanding.

Dr. J. NEWMAN MORRIS (Melbourne) referred to the needs of isolated centres, and the desirability of a continuous medical service. There were no parts of Victoria more than 20 miles from medical aid, and yet medical assistance was greatly welcomed in the relatively remote parts of this state. The Aerial Medical Service involved no encroachment on private practice. The service functioned where no private practice existed.

Dr. G. SIMPSON (Melbourne) remarked on the similarity between the Aerial Medical Service in Australia and the Highlands and Islands service in Northern Scotland. He gave a general description of the method of working of the scheme and, with the aid of lantern slides, described the conditions of life in those parts of Australia served by the service.

A discussion on

Social Aims of Mental Hygiene

was opened by Prof. HARVEY SUTTON (Sydney) who read a paper on the *Child Guidance Clinic*. He said that problems of behaviour, especially bad habits—"the everyday problems of the everyday child"—had long been the subject of discussion. Controversy as to school discipline and corporal punishment seemed to have originated in England with the appearance of grammar schools in the early sixteenth century. In Elizabethan days, schoolmasters showed an implicit belief in the maxim of Solomon: "Spare the rod and spoil the child," and the ability to flog pupils became for over two centuries one of the vocational attributes of the pedagogue. It was thought apparently that the birch tree was the tree of knowledge. Ascham, the tutor of Queen Elizabeth, protested against the universal indiscriminate use of corporal punishment. John Locke, physician, philosopher, and politician, had written a book, in every way modern, on "How to bring up your children." The author was himself a bachelor, and exercised the perennial right of the unmarried to instruct parents in their duties. He showed that corporal punishment was of little value, but it required a generation of universal education to discredit its use. Making the punishment fit the crime by making "the prisoner pent—unwillingly represent—a source of innocent merriment" might prove a solution, for ridicule and shame were, as Locke pointed out, powerful influences. Increasing experience, however, pointed to other methods; just and unemotional criticism, encouragement of good efforts, the selection of sound interesting outlets for energy, and better personal understanding between teacher and pupil. Like the gyroscope, children reacted best to indirect influences. How often did

we find that the longest way round was the shortest way home?

Dr. Sutton dealt with bad habits and their correction. Important amongst these were bed-wetting and masturbation. In regard to the former, the speaker strongly deprecated drug treatment, and emphasised the need for encouragement and sympathetic understanding. Perhaps of all bad habits masturbation was the best example of the failure of ignorance. For years moral propaganda had described the alleged rotten effects on the central nervous system, but now we knew that masturbation was a symptom of mental instability rather than a cause, and that even habitual practice was injurious only to certain special types of person. The frequency of appearance of the male emission was not known. In a group of 100 medical and other university men students investigated, there appeared to be a more or less regular rhythm of some 14 days, becoming more regular after the age of about 21 years. This emission was of course strictly physiological, and illustrated the need of meeting the natural curiosity of the adolescent with simple truthfulness.

Stammering was a constant problem in school life. In New South Wales, about 1 in 40 boys showed disorders of speech, chiefly stammering, whilst in girls the frequency was only about one-third and then not to the same degree. The defect could be a very real nuisance to the individual. The idea of classes and clinics collecting groups of stammerers used to be viewed adversely, but the atmosphere of success and the expert teaching made possible in these clinics more than outweighed any such disadvantage. The proportion of left-handed children amongst stammerers was higher than the proportion in the school population, about five to one. Evidence seemed to show that the left-handed stammerers had been changed to right-hand writers under pressure or penalty—another example of the danger and futility of repressive methods.

Other minor defects might influence the mental and physical progress of the child. Amongst these were defects in vision, hearing, nutrition, congenital heart disease, and so forth. Myopia might lead to the "shut-in personality." Unilateral deafness and colour-blindness often lead to unsuspected mental conflicts.

The doctor's part in assisting the child to adjust his problems was an important one. It was during the pre-school years when the child's character was being formed that the parent especially needed such help from the doctor. The development of child guidance clinics raised several important questions—where should they be located? By whom should they be staffed? What would be their objective? Hospitals were frequently chosen, where the medical control was unquestioned. The Education Department also provided suitable locations. Outside these two official relationships there were private clinics, the best leader being a medical man, with wide sympathies, a deep personal interest in children, and the gift of handling them. The combined physician, paediatrist, psychiatrist, and school doctor should have as his second in command a trained educational psychologist, and the third of the trio was the trained health or home visitor, to evaluate the patients and the home. In conclusion, Dr. Sutton emphasised the importance of biological, physiological, and medical training for those who wished to gain the fullest appreciation of the problems of personality.

Dr. K. S. CUNNINGHAM (Melbourne) recalled the fact that Dr. Sutton had introduced intelligence

tests locally in 1913. As a non-medical man he regarded it as a great privilege to be allowed to join in this discussion. He thought that those who called themselves psychologists should have some qualifications before doing so. In reference to child guidance clinics, all children needed guidance of some sort.

Mr. G. A. OSBORNE (Education Department, Melbourne) said that the policy of the Department was that sex education was definitely taboo in Victorian schools. In reference to discipline, corporal punishment had practically disappeared because of the better understanding between teachers and pupils. There was more real happiness in the work. The Department attributed importance in the make-up of the child not only to heredity, but also to environmental factors, particularly in the pre-school age. Their policy included the provision of more nursery schools and kindergartens, special schools for the mentally deficient, and the encouragement of the formation of school clubs. Specially trained teachers, social workers, and psychologists were essential.

Prof. J. A. GUNN (Melbourne) spoke of the coöperation of the three team-workers mentioned by Dr. Sutton. The training of psychologists was most important, and we were undoubtedly suffering from a plethora of untrained people who assumed the title. There was a large and important tract of country between the normal and the abnormal. One's attitude to life was largely decided by the reaction to fear and to sex.

Dr. R. EMERY (Melbourne) discussed the attitude towards crime and delinquency from the psychiatric viewpoint. The idea that punishment could be useful in the curative treatment of maladjustments was wrong. One's attitude towards crime was largely conditioned by unconscious motives and repressions; there was no such person as an unbiased judge, whilst verdicts might be the expression of subconscious sadism. The study of delinquent children was of great moment.

Dr. J. F. WILLIAMS (Melbourne) recounted his experiences at the psychiatric clinic started by Prof. R. J. A. Berry at the Children's Hospital, Melbourne. Children examined included mentally deficient and emotionally retarded, and those whose physical defects were the real cause of their difficulties. Epileptics were a great problem. He thought that nursery schools were very useful, particularly for the borderline cases.

Prof. W. S. DAWSON (Sydney) thought that in child guidance clinics should be controlled by medical men. There was a great need for the education of both parents and social workers. In reference to the mentally deficient, and also of the dull "normal" child, the development of institutional methods was necessary.

Miss HINLOP (Melbourne) said that her experience as directress of the training of social workers had satisfied her that team-work along the lines suggested by Dr. Sutton was best. She stressed the difficulty of assessing and improving home conditions unless there was a line of approach to the parents other than through the child. Social workers had a very difficult task, and some grounding in the principles of psychiatry was required.

Dr. N. A. ALBISTON (Melbourne) said that the basis of our life depended on the recognition of the family as the social unit. This was affected by such institutions as nursery schools, and there was a danger of the misapplication of principles. He hoped that

the family life would be assisted by the development of the scheme.

The CHAIRMAN commented on the points raised in view of his experiences as a general practitioner and as a medical adviser to a public school. He said that corporal punishment was occasionally necessary in the interests of school discipline, but that the punishment of girls in this way was very rare. The problem of nocturnal enuresis was very difficult; a developmental factor and possibly also some endocrine upset was at work. He agreed with other

speakers that the child should be educated in sex matters by reference to human anatomy and physiology, and not by analogy. The real aspect of the life of the child was formed from the attitude of his parents.

Dr. SUTTON, in a brief response, emphasised that the real function of child guidance clinics was to assist the parents to maintain the integrity of the family unit and promote its harmony. The usurpation of parental function was never intended.

PANEL AND CONTRACT PRACTICE

The Cost of Vaccines

It is sometimes alleged that insured persons receive a standard of treatment below that enjoyed by private patients, and this idea is one which insurance practitioners themselves can do most to dispel. Unfortunately many practitioners, unwittingly no doubt, foster the notion that anything out of the common is beyond the scope of medical benefit. And one of the most common causes of misunderstanding is the administration of injections—vaccines and the like. Sometimes the doctor, anxious to do the right thing, writes to the Insurance Committee something like this: "I have been advised to give a vaccine as a preventive against influenza. Could you please inform me if the vaccine can be obtained through the N.H.I.?" Of course it can and should be given to the patient if the doctor is of the opinion that it is necessary for the proper treatment of his patient.

But it is more unfortunate still when, having agreed to give a certain form of treatment, the doctor causes his patient to incur expense and does not take the trouble to ascertain whether the expense is justified. Here are the salient points of a recent case.

The patient had been suffering from recurrent boils which in spite of treatment with various medicines, local applications, &c., relapsed from time to time. The patient asked the doctor whether there was any other treatment which the doctor could give him, in response to which the practitioner referred to a recently introduced vaccine treatment for staphylococcal infections, saying that as he regarded the treatment as experimental, and not as requisite or necessary, he would not be prepared to issue an insurance prescription for the vaccine, but that if the patient cared to purchase it himself the doctor would apply it free of charge. The particular preparation used was one which could have been either ordered or supplied by the doctor, and the clerk of the committee when telling him so commented upon the doctor's excuse for failing to prescribe it from the point of view that in medical treatment much is of an experimental nature. It seemed to the clerk that, other remedies having been tried and found wanting, there was every justification for ordering the vaccine in this case even though the doctor was not certain that it would have a beneficial effect.

The weakness of the doctor's position in this case was accentuated by the fact that he himself "mentioned" the new treatment and was willing to apply it experimentally at the patient's expense. It would obviously be improper to debit insurance funds with the cost of experimental investigations in therapeutics (although the Medical Research Council's funds actually originated in this way), but to apply a recognised form of treatment experimentally in a particular case is a different proposition. The difficulty was overcome by the doctor authorising the refund to the insured person of the amount paid, and a corresponding debit against his account, but

he is claiming the cost of the preparation from the committee, so no one will be the worse off, and one insured patient at any rate will know that insurance medical treatment is not restricted to what can be obtained in a bottle.

Adequate Prescribing

The annual report for 1934 of the chief medical officer of the Ministry of Health contains a paragraph about insurance prescribing, in which it is pointed out that the regulations impose no restriction on the discretion of a doctor in prescribing medicine for his insurance patients. That discretion, however, must obviously be exercised reasonably, and if on investigation it is found that a doctor's prescribing is causing unreasonable demand on the funds available, money may be withheld from his remuneration. Judgment of the question rests in any case not with the Minister, but with the doctor's professional colleagues on the local panel committee; the Minister has no power to set standards in this matter. The demands on the funds caused by the prescribing of insurance practitioners throughout the country as a whole continue to cause anxiety. The average expenditure for drugs per head of the insured population in 1934 (namely, 3s.) showed no appreciable decrease on that for the previous year. While a certain increased demand is to be expected from the extending use of costly, though necessary, modern methods of treatment it remains, as most observers believe, that a considerable proportion of the total outlay on drugs could be eliminated without detriment (possibly with advantage) to the proper treatment of the people. The report goes on to say that the wide variations in cost noted in the previous report, upon which we commented recently, remain with but little change, the average varying from 55.5 pence in Salford down to 22.6 in Oxford. It is gratifying to be able to state that during the year there was evidence that increasing interest in the question of the general high level of cost of prescribing is being taken by representatives of the profession themselves in various parts of the country. The C.M.O. points out that in a professional matter of this kind the well-directed efforts of representative members and bodies of the profession must prove incalculably more potent than any disciplinary action in individual cases which is open to the department.

The Regional Medical Service

Again it is found that insurance practitioners are averse from calling in the regional medical officer for consultation purposes. For decision as to incapacity the approved societies referred 499,885 cases and doctors 1366 cases, but for consultations the societies referred 2559 and insurance doctors only 82 cases. During the year the R.M.O.'s made 14,991 visits to insurance doctors in connexion with prescribing,

certification of incapacity, and the keeping (in some cases the non-keeping) of medical records.

Medical Records

A practitioner writes: "In a recent Public Health note (THE LANCET, Sept. 28th, p. 740) occurs the sentence, 'Practitioners may still be heard to complain about the record keeping that the insurance medical system imposes upon them, yet when they were students they were taught, as clinical clerks, to note the salient facts of a case for future reference.' As an insurance G.P., may I say that it is not the clinical records we object to so much as the compulsory tick for each attendance and certificate, and the schoolmaster attitude of the inspecting R.M.O., with the threat of a fine if the ticks do not come up to so much per cent. Compulsory ticks should be forthwith abolished, and if the visiting R.M.O. must come round and inspect, let him stick to a survey of clinical records."

To be useful to doctor and patient, records should be consulted each time the patient is seen, and some note made to indicate progress. If it is generally found that the insertion of a mark in one of the columns provided entails any serious extra labour, something should be heard of it at the forthcoming Panel Conference on Nov. 14th. We understand that the Insurance Acts Committee have informed the Ministry of Health that after careful consideration they are convinced that, subject to certain minor alterations in the form of record, the present system of medical records should in all essentials be continued. But the committee have suggested that the profession, through their local committees, should coöperate with the department in measures for improving the clinical, as distinct from the administrative, value of the records where this is found defective. Consideration is being given to an appropriate procedure for carrying the suggestion into effect.

PUBLIC HEALTH

Records of Nutrition in School Life

THE request by the Board of Education that continuous records of nutrition should be kept on the lines followed in the county of Gloucester leads us to turn to Dr. J. Middleton Martin's report as county M.O.H. where his data and methods are explained. He speaks of estimating the "functioning of the body as a whole," and quotes Memo. No. 124 of the Board which begins: "The main issue is to estimate the general well-being of the child," and after giving examples of criteria ends with the remark: "It is the general impression which decides the issue." The Board suggest a grouping into (1) excellent, (2) normal, (3) slightly subnormal, (4) bad; the four groups in the Gloucestershire report probably denote similar grades. In either case the classification depends mainly on the personal impression formed by the examining doctors. Dr. Martin regards the average weight and height for age determined for his school-children in the years 1909-1918 as a serviceable check, but the relation of weight to age is hardly of much value as a standard of nutrition. He cites examples of

wide discrepancies between observers, adding that in the first 12 years of the series there were ten changes in the medical staff, although for the last 14 years the personnel of four has been the same. In his view these individual variations are so blended in the mass of figures that the combined findings may fairly represent the nutritional trend in the county as a whole. Support for this view will be found in the fact that in all the different age and sex groups the changes

have been similar, and that there is a close coincidence between the periods of rise in the "above average" group with a fall in the "below average" group. We reproduce here the three of Dr. Martin's graphs which concern boys. The numbers for each year are of course not large; the total routine medical inspections in the county in 1934 were less than 1300, compared with over 200,000 for London, and the effect of minor errors in the records is enhanced by their subdivision into six sections according to sex and age grouping. But the Gloucestershire records cover a period of 26 years, and Dr. Martin notes that the London figures for 1920-33 show a similar rise and fall. They are moreover fairly consistent in the various groups, and they do demonstrate

Nutrition of School-children in Gloucestershire.

Percentages (boys) above the average (continuous line) and below the average (dotted line).

that the general nutrition tended (1) to improve just before and during the war, (2) then to fall somewhat, and (3) to improve fairly regularly during the past 12 years.

These tendencies are in part confirmed by the records of other areas. They differ however from those of Dr. Friend in his recent work¹ on the nutrition of public schoolboys, the condition of whom was markedly worse during the war years. Naturally the effect of the war on the financial resources of the families of elementary and public school-children was not the same. The example of Gloucestershire might well be followed by other authorities which have not heretofore kept such records and can benefit by the experience already gained in the avoidance of possible sources of error.

New Public Health Legislation

Parliament is likely to be prorogued this week, which will mean the postponement of the big new Public Health Bill. This is the measure which will repeal and replace the existing legislation which goes back to 1875 (when both the central and the local authorities were different from those of to-day) and was greatly extended in 1907 and 1925. It will perform for public health the same admirable work as was done for local government when the consolidating Local Government Act was passed a few years ago. As on that occasion, it will doubtless be found that some new provisions must be enacted for the sake of symmetry and to remove uncertainties. It is to be hoped that members of Parliament will not wreck the chances of the Bill, which is primarily a redrafting Bill, by overloading it with amendments of their own. The committee which has produced the new draft was appointed by the Minister of Health in 1930. It has produced visible results more swiftly than that other body which the Chancellor of the Exchequer appointed several years earlier to consolidate the law of income-tax. When the Public Health and Local Government Consolidation Committee held a dinner to celebrate the completion of its work on the Local Government Bill, Lord Chelmsford was still its chairman. At his death Lord Addington, who has considerable experience of local government matters, was appointed to succeed him. Although the proposed new legislation means that medical officers of health and others will have to learn their way about a new code and probably to supply themselves with a new text-book, the general interest of all in public health will be stimulated and assisted by giving the citizen a single modern document in which the law may be found.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 12TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2839; diphtheria, 1218; enteric fever, 37; acute pneumonia (primary or influenzal), 530; puerperal fever, 46; puerperal pyrexia, 121; cerebrospinal fever, 10; acute poliomyelitis, 14; acute polio-encephalitis, 2; encephalitis lethargica, 7; dysentery, 26; ophthalmia neonatorum, 95. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Oct. 18th was 2955, which included: Scarlet fever, 1035; diphtheria, 1156; measles, 36; whooping-cough, 293; puerperal fever, 17 mothers (plus 8 babies);

encephalitis lethargica, 268; poliomyelitis, 15. At St. Margaret's Hospital there were 24 babies (plus 11 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 3 (0) from measles, 6 (1) from scarlet fever, 14 (3) from whooping-cough, 25 (7) from diphtheria, 41 (11) from diarrhoea and enteritis under two years, and 21 (5) from influenza. The figures in parentheses are those for London itself.

Southampton reported the only death from enteric fever. Liverpool and Birmingham had each 4 fatal cases of enteritis; no other great town more than 2. The deaths from measles occurred at Liverpool 2, Manchester 1.

The number of stillbirths notified during the week was 290 (corresponding to a rate of 44 per 1000 total births), including 44 in London.

MEDICINE AND THE LAW

Suggested Road Traffic Courts

At the Law Society's provincial meeting at Hastings last month a speaker advocated the creation of separate "road traffic courts" with civil and criminal jurisdiction. He thought that some 500 courts would be required, with a traffic judge and traffic registrar sitting concurrently in each—presumably on the lines of our existing county courts. The creation of such courts, he opined, might hasten the decrease of the coroner's court, a result which, in his opinion, would be a blessing to all.

There is no doubt that the High Court in London is at present heavily preoccupied with claims for damages in what are called "running-down cases" and that, if these could be tried elsewhere, much judicial time would be set free for other kinds of litigation. Not only would the arrears in the King's Bench Division vanish; the courts of summary jurisdiction also would be relieved of the thousands of summonses against motorists which the last volume of Criminal Statistics showed to be a great part of the magistrate's work. There seems, however, no need to belittle the services of the coroners' courts. Unlike other juries, the coroner's jury is allowed not only to reach its conclusions in the light of the evidence offered at the hearing, but also to bring to the case its own knowledge of local conditions and circumstances. It may well have some special contribution to make by recommending that a traffic crossing known to be dangerous shall be made more safe or that existing warnings or notices be improved. In any event the inquest system needs to be considered as a whole and not merely by reference to a fraction of its activities. It will be time enough to talk of ending the coroner's court when the departmental committee, now examining the practice and procedure at inquests, decides to advocate termination.

Psychiatry in Schools of Law

Are there any courses at English universities where law students may familiarise themselves with psychiatry? In America the University of Yale has instituted such a course long enough for it to be recognised part of the work of the Yale Law School. The medical faculty of the university has produced in Dr. Kahn a teacher who has specialised in criminology. He and Dr. Thompson, of the Department of Psychiatry in the School of Medicine, have coöperated with the teachers of law, and the police authorities send actual cases for clinical demonstration. There is a seminar study of various medico-legal problems raised

¹ Friend, G. E.: *The Schoolboy*. Cambridge. 1935. See THE LANCET, 1935, I, 1394.

by abnormal personalities in both adult and juvenile delinquents. The students, it is believed, undertake research into the patients' environment and pedigree. It is realised of course that useful conclusions cannot be reached without prolonged observation and that two hours weekly cannot fully equip the student. Nevertheless, the group discussions, open to a limited number of law students with the consent of the instructors, will do something to acquaint future judges with the possibilities of a science which courts of law ought not to neglect. We have police magistrates in London who have recognised the value of psychiatry; others are inclined to be contemptuous. The Home Office has begun (as the annual reports of the Prison Commissioners have revealed) to make a tentative use of psychiatrists in selected cases of difficulty. It has not yet admitted the success of the experiment.

IRELAND

(FROM OUR OWN CORRESPONDENT)

A BELFAST HOSPITAL AND ITS TRADITIONS

IN an address delivered at the opening of the new session at the Royal Victoria Hospital, Belfast, Dr. Robert Marshall told something of the history of the hospital which the students had come to serve. In 1792, which marked its beginning, Belfast was a small town of 18,000 inhabitants, described as "unusually picturesque and beautiful—the pleasantest spot in the north of Ireland." In that year representative citizens appealed for funds to found a general dispensary for the sick poor. The first honorary staff consisted of two consulting physicians, two attending physicians, and two attending surgeons, and it was interesting to note that pending the election of Mr. Hull as apothecary at £40 a year, the surgeons were expected to dispense medicines for the physicians. This dispensary, the first of its kind in the city, had a troubled career until the year 1799, when a fresh start was made and three houses in Smithfield were rented, Dr. McDonnell and Mr. Fuller being appointed physician and surgeon respectively. The hospital steadily gained the appreciation of the public and in 1810 McDonnell and his colleagues obtained promise of a site of ground in Frederick Street. The first patients were admitted on August 1st, 1817, and in 1820 the admission of pupils was authorised; but it was not until 1882 that James Alexander Lindsay was appointed the first house physician. The speaker emphasised that this system of resident pupilship had been for over a century the distinctive feature of Irish medical teaching and advised the students to avail themselves of this opportunity, because it was the most important part of their course.

The year 1827 marked another stage in the history for it was in that year that Dr. McDonnell gave the first formal clinical lecture on the subject of systematic medicine. The need for a medical school was then keenly felt, but it was not until the autumn of 1835, exactly a hundred years ago, that this was opened in the Royal Belfast Academical Institution. The first professor of medicine, Dr. Henry MacCormac, was chiefly remembered because he was the first to insist on fresh air in the treatment of tuberculosis. He was a man of great erudition, conversant with 20 languages, and received a public testimonial to his work for the sick poor during the cholera epidemic of 1832.

Dr. Marshall then referred to the life and death

in 1845 of Dr. McDonnell who must always be revered as the founder of the hospital. During his lifetime he had, largely by his own enthusiasm, erected the hospital and the medical school of which it was a part. In 1903 the present hospital was opened at a cost of £120,000. He also spoke of some of the great ones who were the teachers in the past: Sir William Whitla, Sir John Byers, Sir John Walton Browne, Dr. Lindsay, Dr. McQuitty, Dr. McKisack, Dr. McIlwaine, Mr. Robert Campbell, and Mr. Andrew Fullerton. He reminded them of the terms in which the hospital had been dedicated—"to the sick and to the art of medicine." The sick man came first and the art of medicine second.

Prof. R. J. Johnstone presided at the meeting and a vote of thanks was proposed by Mr. Hardy Greer and seconded by Dr. J. C. Rankin. In the course of his address Dr. Marshall referred to the appointment of Mr. T. S. Kirk as consulting surgeon, after years of devoted service, and said that Mr. H. P. Malcolm had been promoted surgeon and Mr. C. A. Calvert elected assistant surgeon. The board of management have made three notable achievements in the past years—namely, a new nurse's home and a pavilion for private patients, which were in the course of erection, and a superannuation scheme for the nursing staff.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The annual meeting of the president and fellows of the Royal College of Physicians of Ireland was held in Dublin on the afternoon of St. Luke's Day. Dr. John Agar Matson was re-elected president of the College. The following were elected censors: in medicine, Drs. J. F. O'Donnell and E. T. Freeman; in midwifery, Dr. N. McI. Falkiner; in medical jurisprudence, Dr. P. T. O'Farrell. The annual dinner of the College was held on the evening of the following day, when 25 fellows and 65 guests dined together.

BELFAST POLICE SURGEON'S DEATH

Dr. P. E. O'Flaherty, who died on Oct. 14th after a short illness, was senior police surgeon in Belfast. Educated at St. Malachy's College he graduated in medicine through the old Royal University of Ireland and set up practice in Belfast. For some years he was a member of the clinical teaching staff of the Mater Infirmorum Hospital. Later he was appointed medical officer to H.M. Prison and the Royal Irish Constabulary in which offices he had over 20 years' service. Dr. O'Flaherty was popular among his professional brethren and the general public and his loss will be deeply regretted.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

CHANGES AND CULTS

THE 199th session of the Royal Medical Society opened last week when Sir Walter Langdon-Brown delivered an address on *Changing Conceptions of Disease*. Dr. J. L. Henderson, senior president of the society, was in the chair. Sir Walter began by recalling his first visit to Edinburgh as a student 45 years ago, and paid a graceful tribute to the Scottish capital in respect to both literature and medicine. He proceeded to remind his audience of the debt medicine owes to the genius of the Greeks. The development of medical knowledge might be compared to a spiral, which though tending to ascend

has frequent opportunities of looking back at knowledge which was gained long ago and has since been forgotten. It is often found that discredited views have much to be said in their favour, and while some might describe this as the swing of a pendulum, the analogy of the spiral is more correct. The lecturer then described the changes caused in medicine by the development of biochemistry which has done much to bring to light the deficiency diseases. He emphasised the danger of the medical profession forming ill-considered conclusions, and illustrated this danger by speaking of the changing views of viscerophtosis during his own lifetime. The medical profession, he said, is apt to develop cults, such as that which

considers excess of uric acid in the blood to be a cause of many ills. This cult had developed to such an extent that he had heard a physician express the belief that a man never completely gets over the effects of eating a rump steak. Uric acid was now known to have little or no poisonous effect on the body. The importance of psychological disturbances in causation of many forms of disease, especially those affecting the alimentary system, had been one of the most important advances of post-war medicine.

Sir Walter was given an enthusiastic vote of thanks, proposed by Prof. W. T. Ritchie and seconded by Dr. K. M. Morris. The session could scarcely have had a more interesting or entertaining beginning.

CORRESPONDENCE

COUGH AND HUMIDITY

To the Editor of THE LANCET

SIR,—In a London infirmary, where I treated consumptives for many years, I was much struck by the variations in the amount of coughing heard in the ward and by the marked influence of changes of weather. It has been said that in phthisis every cough is a tragedy, and it should certainly be the aim of the physician to stop all useless coughing if he can.

In designing wards for the treatment of consumption very little attention is directed towards the production of a suitable degree of humidity, though the ward temperatures are charted with solemn regularity. I have noticed that cold dry nights in the winter are often more troublesome as far as coughing is concerned than "muggy" nights, even if the latter contain their quota of fog. I imagine that the explanation is somewhat as follows. Cold air, entering by the windows, has a low moisture content. In passing over the radiators it is heated many degrees but its water content remains the same. By reason of the rise in its temperature the air has now a much greater drying power so that when inhaled it dries and irritates the throat and air passages. By using wet and dry bulb thermometers, I collected figures illustrating this point, coughs in a ward of 28 beds being recorded by a nurse over half-hour periods, when it was evident that there was more coughing when the air in the ward was many degrees warmer than the outside air.

It therefore seems desirable that, when these conditions obtain, the humidity of the air should be increased artificially to a degree most suitable for patients. It is not desirable to produce "muggy" air, for this is known to be harmful to consumptives. Masten states that for most tuberculous cases the temperature range should be between 38° and 68° F. with a humidity not exceeding 50 per cent.

I am, Sir, yours faithfully,

Buxton, Oct. 15th.

G. C. PETHER.

INVERSION OF THE UTERUS

To the Editor of THE LANCET

SIR,—Mr. James Cook's note in your last issue (p. 884) on complete inversion of the uterus leads me to report the following case which I saw on August 19th, 1934.

A primipara, aged 24 years, had had an easy low forceps delivery. Her own doctor and a qualified midwife were in attendance. About ten minutes after the infant was born the mother had a violent pain, and the uterus with the placenta attached was expelled. I saw the patient

half an hour after this occurrence. There was definitely no history of traction on the cord after delivery of the child, nor, as the cord was of normal length, was it likely that traction had been exerted on it, between the pains, during the forceps delivery, and as the fundus had not been manipulated, it was apparently a case of spontaneous inversion of the uterus.

The patient was profoundly shocked, the pulse being hardly perceptible and impossible to count. There was very little hæmorrhage; 1 c.cm. of Coramine was immediately given, together with the usual treatment for shock. The placenta was then detached from the surface of the uterus which was immediately well washed with Dettol solution.

The uterus was easily replaced without an anæsthetic, 1 c.cm. of pituitrin given, and an iodine douche administered. The uterus was then well contracted. On the second day the temperature rose to 100° F. and remained at this level, with variations of half a degree for seven days. Antistreptococcal serum and dettol douches were given, and an uneventful recovery was made.

This case supports Mr. Cook's suggestion that early reduction of the inversion is important. The confinement took place in the patient's house, and removal to hospital would have necessitated a journey of six miles, with consequent delay in treatment and possible disaster to the patient. As the amount of hæmorrhage is generally said to depend on whether the placenta is separated or not, it was interesting to note that the removal of the placenta did not materially increase the hæmorrhage.

I am, Sir, yours faithfully,

Stourbridge, Oct. 18th. C. J. CHESTERFIELD COOKE.

URINARY FISTULA FOLLOWING APPENDICECTOMY

To the Editor of THE LANCET

SIR,—Since apparently very few instances of urinary fistula following appendicectomy have been recorded the following case may be of interest to surgeons.

A very fat woman, aged 45, was operated upon for acute appendicitis, the abdomen being opened by a lower right paramedian incision, and a perforated gangrenous retrocaecal appendix removed. A length of corrugated rubber dam was left draining the pouch of Douglas and was brought out of the abdominal wound at its lower extremity. The patient was nursed in the high Fowler position. On the fifth day following the operation the dressings were reported to have an ammoniacal smell. It was suggested that the ureter or the bladder had been injured during the operation or that the pressure of the drain had caused a portion of the bladder wall to slough. There remained, however, the onus of proof

that the suspected fluid was in fact urine. The flow was not great enough to enable any to be collected for examination, so indigo-carmino was injected intravenously and shortly afterwards the dressings at the lower angle of the wound were seen to be stained blue. The patient died of general peritonitis. At autopsy the whole intestinal tract was grossly distended. There was no free fluid in the general peritoneal cavity and no intraperitoneal staining. A probe passed into the bladder emerged at the lower end of the wound and on further dissection a patent urachus extending up to the wound was displayed. It is believed that the explanation of the fistula is as follows: either the patent tract was punctured by a needle in picking up the inner leaf of peritoneum while closing this layer, or possibly the tube may have caused necrosis by pressure, in support of which is the observation that the urine did not begin to escape until the fifth day after the operation.

This latter observation raises the question of the best site of emergence of drainage-tube or dam in cases of incisions below the umbilicus whenever drainage has yet to be employed. As far as I can ascertain most surgeons bring the drain out through the lower angle of the wound; but it was pointed out to me by Mr. Frankau that this was bad practice, for the following reason. It is generally agreed that the point of emergence of a drain may leave a weak spot, and this cannot be satisfactorily controlled by any form of belt if it is at the lower end of an incision in this region; whereas, at the upper (umbilical end) a belt can readily be fitted. Two lesser advantages may possibly also be claimed for bringing the drain out of the upper end of incisions made below the umbilicus, but I do not wish to give them the same emphasis: (1) if draining through Battle's pararectal incision there is less likelihood of a secondary hæmorrhage from pressure on the deep epigastric vessels, and (2) if corrugated dam is used it will separate omentum and intestine from the back of the peritoneal suture line as it lies in the length of the wound, and so perhaps diminish the chance of adhesion formation.

I am, Sir, yours faithfully,

VICTOR RIDDELL,

Surgical Chief Assistant, St. George's Hospital, S.W.
Oct. 22nd.

A PECULIAR BODILY DISPROPORTION

To the Editor of THE LANCET

SIR,—The significance of external physical characters has received relatively little consideration, except where gross disproportion, amounting to deformity, is present. And I should not have asked you to give space to this preliminary communication on the subject if a question put to me by H.M. coroner for the metropolitan district of Essex had not caused the lay press to call attention to the subject. A series of measurements on a post-mortem population of about 500 bodies has, I think, revealed a peculiar correlation between the "trunk-leg ratio" and certain other abnormalities.

In 17 cases the leg-length, measured from the top of the great trochanter to the heel, was greater than the trunk length, measured from the top of the great trochanter to the vertex. In all these persons I found that—

1. The aorta was strikingly narrow;
2. The thymus gland was present, and varied in weight from $\frac{1}{4}$ oz. to $1\frac{1}{4}$ oz.;
3. The spleen was rather large, and the Malpighian bodies were strikingly prominent;

4. The mesenteric glands were unusually large and numerous.

Two of the cases were sudden deaths under anaesthesia, and the other 15 were suicides. Now, these 15 cases represent 75 per cent. of the total cases of poisoning in the age-groups 14 to 35 in my whole post-mortem population. It seems clear, therefore, that, either 75 per cent. of the population of this country in this age-group possesses these characteristics, or that persons of this type have such mental characters as may lead to suicide. But I possess records of 101 bodies between the ages of 14 and 35 in which death was not due to suicide or anaesthesia; and only 4 of these showed the external and internal peculiarities to which I am calling attention. This small number of persons showing such characters in the second group does suggest that the first group consists of abnormal persons.

Later I hope to present the findings in detail, but the thesis I wish to defend here is that persons with leg-length more than 50 per cent. of the total body-length are liable to sudden death under anaesthesia and, further, that persons of this type are potentially suicidal. It also appears to be justifiable to state that persons with this external peculiarity will be found to possess an excess of lymphatic tissue. A striking manifestation of this excess is the presence of thymic tissue at an age when it would normally have disappeared (after the age of 14 years).

It seems to me possible that some anaesthetic deaths would be avoided if measurements were taken before anaesthesia were started. It would also be valuable to know whether this peculiar bodily disproportion is commoner among the inmates of mental hospitals than in the general population.

I am, Sir, yours faithfully,

Park-square West, N.W., Oct. 17th.

A. PINEX.

ATTITUDE OF SURGERY TO HÆMATEMESIS

To the Editor of THE LANCET

SIR,—I am flattered that any words penned by me should attract the attention of such a distinguished and erudite physician as Dr. Lothby Tidy; furthermore, I rejoice to find that his peroration coincides almost verbatim with one of the opening paragraphs in the address published by me in THE LANCET of Oct. 12th, and that he too urges "the treatment of each case individually, with an open mind, and with the coöperation of medical and surgical acumen." This indeed is the very burden of my paper, a closer liaison between physician and surgeon in these difficult cases. I trust that the weight of Dr. Tidy's authority may promote that coöperation and consultation that we both desire.

A second glance at my paper should demonstrate to Dr. Tidy that the indications for surgical interference are clearly and fully set out therein; he will also find figures of my own, should he care to read. Of personal cases of hæmatemesis which have been admitted straight into my own wards or into private institutions I find that in point of fact I operate upon little more than one-third; difficulties in diagnosis, the general condition of the patient, and all that constitutes surgical judgment seem to deter me from interfering in a higher percentage; nevertheless, this small figure may not constitute the ideal. If Dr. Tidy will explore the possibilities of the blood-drip and early operation in the hæmorrhages of chronic ulcer, and if he will summon surgical aid in the first 24 hours, he will find anxieties slip off his shoulders.

There is, however, one further paragraph in his letter that cogently demands an answer, for he writes :

"Such a statement is manifestly absurd, and a study of Finsterer's original article gives the impression of the same exaggeration throughout. Neither his statements nor his statistics can be safely accepted nor deductions drawn from them."

Those who know their Herodotus and who recall the description given by the historian of Halicarnassus regarding certain pristine customs of an ancient people, will regret with me that a censor of the Royal College of Physicians should metaphorically resort to similar practices in his references to Prof. Hans Finsterer. Bonds of a long and intimate friendship with the Austrian professor compel me to protest indignantly against the charge of unreliability levelled against the distinguished surgeon—a surgeon of international repute, whom doubtless Dr. Tidy knows not, and almost certainly has never seen at work.

Surgeons all over the world are nowadays a band of brothers; the numerous surgical travelling clubs of this land which are constantly visiting continental clinics have done much to consolidate that spirit of fraternity. In the name of British surgery and especially in the name of the many British surgeons who have journeyed to Vienna, who have spent time with the professor, and who have seen this kindly, honest surgeon at work, I deprecate these reflexions on the value of his statements and figures.

I am, Sir, yours faithfully,

Harley-street, W., Oct. 21st. G. GORDON-TAYLOR.

To the Editor of THE LANCET

SIR,—I do not wish to enter into the discussion on the attitude of surgery to hæmatemesis, but I was astonished to read the attack of Dr. Tidy on Prof. Finsterer, his statistics and conclusions therefrom. It is extraordinary that in a discussion like this Dr. Tidy (who obviously does not know Finsterer or his work) should dismiss the work of one who to those who know him professionally and personally is not only a great worker in the cause of progress in gastric surgery, but is also the very soul of honour as regards the truth of his statistics.

As one who has known Finsterer for many years and has visited and worked with him frequently may I assure Dr. Tidy that Finsterer's statistics can be safely accepted and that in his hands and with his methods the operation gives the results he claims. I have discussed this hæmatemesis question with him on several occasions and have seen some of his cases and the results I have seen bear out the statistics.

I am, Sir, yours faithfully,

Nottingham, Oct. 21st. W. F. NEIL.

To the Editor of THE LANCET

SIR,—I, in common with many of my friends and colleagues, have enjoyed the hospitality of Prof. Finsterer in Vienna. He has with me, as with many other visitors, willingly shared his experience and demonstrated beyond any doubt the safety and certainty of his technique. We went in doubt, we saw with appreciation, and the conviction which naturally followed was real enough profoundly to modify our own technique. It is therefore impossible to allow the comments on Prof. Finsterer's fundamental honesty, made by so distinguished a physician as Dr. Letheby Tidy, to pass without protest. My

concern is, I am sure, shared by many others whose experience has been similar to mine.

I am, Sir, yours faithfully,

HENRY W. S. WRIGHT.

Weymouth-street, W., Oct. 21st.

To the Editor of THE LANCET

SIR,—Anyone who has been fortunate enough to see Prof. Hans Finsterer treating a case of severe hæmatemesis by "immediate operation" would scarcely be inclined to endorse the attitude that Dr. Letheby Tidy adopted in his letter to your journal last week. We are all aware that the interpretation of medical and surgical statistics is open to some criticism, but I would be very hesitant to agree with the suggestion that neither the statements nor statistics of this celebrated surgeon can be safely accepted. Those patients of Prof. Finsterer's that I have seen in this connexion were ample testimony to his teaching. As little delay as possible, a most meticulously careful operation under local anaesthesia, and avoidance of traction on bowel and mesentery were the principal lessons that I brought away with me.

I am, Sir, yours faithfully,

Harley-street, W., Oct. 21st. T. HOLMES SELLORS.

To the Editor of THE LANCET

SIR,—Dr. Tidy's letter prompts me to offer a comment on Mr. Gordon-Taylor's indications for surgery in hæmatemesis—those given in the body of his paper as distinct from his peroration. I agree that the drip method of giving a large blood transfusion promises to make the treatment of "severe" hæmatemesis a more straightforward and less anxious matter than it has been. Let every severe case be so transfused at once; and let every case (cirrhosis excepted) in which pulse-rate, clinical condition, and hæmoglobin estimations indicate the persistence of copious bleeding be operated on while the transfusion continues. The results of following that working rule will teach us more than any further elaboration of old statistics, such as Dr. Tidy asks for.

I should not assume out of hand, however, that drip transfusion will make all gastric operations on the recently exsanguinated equally safe. Where I ask the surgeon to intervene I should still beg him to stay the bleeding with the minimum procedure—e.g., the ligation of arteries rather than resection of the stomach. The latter, if indicated, can usually wait for a few weeks. So also can most of the operations (for large or adherent or long-standing ulceration, for hour-glass stomach, &c.) listed under Mr. Gordon-Taylor's number 4. These operations will often be gastrectomies, and although the large drip transfusion may restore the patient's hæmoglobin to normal within 48 hours after his hæmatemesis, it does not follow that the patient himself is then in the best condition to undergo a gastrectomy. Rest and suitable feeding may well improve him further and so reduce the surgical risk. There is a danger that the new transfusion method may be discredited if too much is asked of it.

I am, Sir, yours faithfully,

R. S. AITKEN.

British Postgraduate Medical School, Oct. 21st.

PRINCESS MARGARET ROSE HOSPITAL FOR CRIPPLED CHILDREN, EDINBURGH.—Plans for the erection of a new ward at this hospital have been passed at the Dean of Guild court. The ward will cost £5500 and will accommodate 25 children, thus bringing the capacity of the institution up to 100.

THE HEALTH RESORT AS NATIONAL ASSET

A CONFERENCE IN BRUSSELS

SOME striking observations on the social and economic aspects of watering-places were made by Prof. RENÉ WYBAUW in a presidential address to the International Society of Medical Hydrology which held its annual meeting in Brussels from Oct. 12th to 17th. In these days, he said, it is the economic argument that appeals to governments and public bodies, and he recalled an investigation he had made in 1912 to discover the effect of additional publicity on a health resort. He had been astonished to find that when the town of Spa and its establishments increased their receipts by 29,000 gold francs the gain to the State (through railways, post office, &c.) amounted to 265,000 francs. Similar investigations at Ostend confirmed this conclusion—namely, that the State received ten times as much as the spa which spent the money. Post-war experiments at Spa produced the staggering information that this little town, receiving nothing from the State in exchange, simply by the intelligent use of its natural waters, brought to the Belgian Government an income of 12 million francs, not to mention 3 million in taxes on games. This calculation could be repeated for all the spas of the world. In certain countries indeed the governments had acquired the spas for themselves. Thus the most beautiful spa in the west of Europe, Vichy, belonged to the French Government, which administered it through a powerful company; Aix-les-Bains had just been endowed with a splendid establishment; Nauheim belonged to Hesse, and Kissingen and Reichenhall to Bavaria, and these have had magnificent establishments constructed for them by the Government. In Poland, Czechoslovakia, and Yugoslavia similar examples were to be found; in Italy the luxurious Salsomaggiore belonged to the State, and even in the little country of Luxembourg Mondorf was State-owned. In other countries taxes were instituted which covered publicity; elsewhere, again, important reductions were given on the railways to all travellers to the spas. In short, the "thermal industry" was everywhere encouraged on account of the large receipts which it brought to the State. Except, however, in certain countries where the governments were actual proprietors, there was a conspicuous disproportion between any sacrifice made by the State for the spas and the enormous receipts received by it through those spas. In Belgium just before the war the Government was much interested in Spa, formed a commission to study its needs, and took upon itself the expense of necessary new work at the establishments. After the war the broken establishments were put in order by the Government. But the anomaly remains, that the State now receives twelve times more in receipts through this spa than those who pay the costs of upkeep, and that it takes no regular share in the necessary expenses, although a new sympathy and understanding is happily gradually emerging.

On the medical and philanthropic sides, said Prof. Wybauw, diseases which pharmacological remedies cannot touch, such as rheumatism and circulatory troubles, are now being successfully treated at the spas. Unfortunately the expense is great, and in many countries, such as France, Germany, Switzerland, and England, an effort is being made to make the spas accessible to the purses of all citizens. The

height of "thermal organisation" is in Soviet Russia, where these cures are obligatory and where sickness insurance includes treatment at the spas as one of the most important elements of public health. Nowadays such charges cannot be imposed on the localities, and the State should undertake and organise the thermal treatment of the poor. The problems are vast, and the nations have need of the coöperation, the skill, and the research of their hydrologists. The situation also has its dangers. The mixture of purely scientific with economic interests sometimes raises issues between different nations in which the high purpose of scientific research is imperilled. In spite of the national egoisms of the present age, he trusted that the members of the society, in addition to searching after knowledge, would always cultivate a wide spirit of humanity and develop all those things which unite men of goodwill.

In welcoming the society to Brussels on behalf of the Minister of the Interior and of Hygiene, Dr. TIMBAL said that countries which realised the importance of their medicinal springs and made the necessary sacrifices for their development created thereby a factor of great importance in national prosperity. The valuable methods used must not be reserved for a privileged class. On behalf of the University of Brussels Prof. HÉGER-GILBERT, its administrator, welcomed the society as a body which was labouring to detach from empiricism a branch of medicine particularly fruitful in therapeutic results.

OTHER SUBJECTS DISCUSSED

The reports and discussions of the conference covered an unusually wide ground.

Dr. W. G. WILLOUGHBY (Eastbourne) in a paper on Marine Therapy described a novel method for continuous readings of relative humidity, showing that the proportion might vary in one day from 20 per cent. to 80 per cent. He said that inquiries from convalescent homes for children go to show that "seaside conditions" have a specific effect on ~~saturnal~~ affections and cervical gland enlargements.

Several papers dealt with Carbo-gaseous Baths. Drs. GUILLEAUME and MARCEL WYBAUW (Spa) contributed a physiological and clinical study with extensive recent bibliography. Dr. WAUCHER (Nauheim) emphasised the increased circulation and capillary activity, apparently due to the formation of a histamine-like substance in the skin; and Dr. DESCHAMPS (Royat) dwelt on the disappearance of arterial spasm and the cumulative and persistent effects of such baths on the circulation.

In a discussion on the therapeutic action of Peloids (semi-solid bath media) the veteran Prof. SCHENK (Belgrade) described and illustrated the formation of the Russian *limans*, the composition of the muds and their irritant action on the skin. Diluted mud baths and packs (*médallions*) are much used in the Soviet Republics for the painful *maladies* "which transform the workers into invalids," and so contribute to the solution of a serious social problem. Prof. PRISANI (Montecatini) distinguished volcanic peloids (*fangi*) as stimulant, solvent, or sedative, each having its own indications, and described recent research work in Italy. Dr. LENOCK (Prague) discoursed on the peats first used medically in Czechoslovakia just a hundred years ago. Dr. W. BENADE said that peloids were now examined at the Geological Institute at Berlin, especially in regard to their organic contents and reaction, varying from 0.1 to 9.0 pH, as well as their plasticity, water-holding capacity, thermal conductivity, and retentivity, and the amount of heat which can be transferred to the body in the peloid bath or pack.

At the general meeting of members resolutions were passed on the subject of Medical Ethics for Spa Practitioners, as recommended in the society's

journal, the *Archives of Medical Hydrology*, last July. The report of the standard measurements committee, presented by Mr. JUDD LEWIS, D.Sc., was received and the name "peloids" adopted, defined, and divided into a fourfold "fundamental classification."

After visits to Spa and Luxembourg the meetings concluded with a luncheon and discussion at the Palais des Thermes at Ostend.

LONDON MEDICAL EXHIBITION

THIS exhibition was opened on Monday and will remain open until 6.30 P.M. on Friday. Over 150 exhibitors took part and the stands were attractively displayed. A brief notice of some of the many products on view is given below.

Drugs and Pharmaceutical Preparations

(90) ALLEN AND HANBURYS LTD. (Bethnal Green, E.), in addition to their wide range of standard products, introduced a number of new preparations, including Calcydic, granules containing dicalcium phosphate, vitamin D, and glucose in a chocolate-flavoured base; Alkagen Glucose granules containing magnesium hydroxide with glucose and oil of peppermint; Proctocaine, a local anæsthetic; and Tannic Acid Jelly for burns.—(61) THE ANGIER CHEMICAL CO., LTD. (86, Clerkenwell-road, E.C.), showed their familiar emulsion, and emphasised the value of their Sagradol laxative emulsion containing mineral oil and cascara perfectly blended.—(116) THE ANGLO-FRENCH DRUG CO., LTD. (11 and 12, Guilford-street, W.C.), showed a number of pharmaceutical preparations, new and old, also the products of Modern Pharmaceuticals Ltd. (12, Guilford-street, W.C.), and especially noted Phospho-Soda (Fleet), a non-toxic, highly concentrated aqueous solution of the primary sodium phosphate, free from syrup, glycerin, or oil; it can be used to correct hyperacidity and constipation and promotes the general functions of the liver and intestinal muscles.—(19) ANTIBODY PRODUCTS LIMITED (Watford, Herts) had on view a new preparation, British Grass Pollen, for the desensitisation treatment of hay-fever and British Bee Venom for rheumatism which, they recommend, should be used in conjunction with Antibacsyn for rheumatoid arthritis.—(7) ARMOUR AND COMPANY, LTD. (Armour House, St. Martin's-le-Grand, E.C.), showed their range of well-known gland preparations, including liver extract and pituitary posterior lobe ampoules.—(44) BAYER PRODUCTS LTD. (Africa House, Kingsway, W.C.) selected for mention a new vitamin-C preparation, Cantan, used for infant anæmia as well as scurvy; Bioferol, a new nutrient tonic of hæmoglobin, iron, and liver, for children and convalescents; and Festan, a stable preparation of pancreatic enzymes in dragées coated with an acid-resistant substance, for the treatment of intestinal affections and to free the intestine of gas before X ray investigation.—(5) BENGUE AND CO., LTD. (24, Fitzroy-street, W.1), stressed Cytobiase, an extract of fresh cod liver in a glycerin base; Iodeopirine, a non-toxic iodine preparation combined with acetylsalicylic acid with an activity 20 times greater than that of the acetylsalicylates; and Noseptyl, a mixture of ephedrine, menthol, and pine maritime in a paraffin base.—(87) BISODOL LTD. and ANADIN LTD. (12, Chancery-street, W.C.) showed their well-known products for indigestion and headache.

(37) BOOTS PURE DRUG CO., LTD. (Nottingham), in addition to their familiar Novostab, Stabilarsan, and Sulphostab, reminded visitors of their Hepastab, a liver extract for intramuscular injection, and their Insulin (Boots), accurately standardised and sterilised; and introduced Sodium Mandelate (Boots) for the treatment of urinary infections without preliminary neutralisation.—(122) BRITISH COD-LIVER OIL PRO-

DUCTERS (HULL) LTD. (St. Andrew's Dock, Hull) emphasised the guaranteed quality and potency of their product and showed visitors photographs illustrating the care which is taken to maintain perfect hygiene throughout the preparation, from the trawler to the bottle.—(140) BRITISH DRUG HOUSES LTD. (Graham-street, City-road, N.) showed their sex hormone preparations, notably Estroform, Estroform "B," and Progestin B.D.H. and the new Gonan, an exceptionally pure standardised preparation of the gonadotropic hormone from the urine of pregnancy; Ergometrine, a quickly acting water-soluble alkaloid of ergot; the Mandelic Acid B.D.H. Outfit designed to facilitate the use of the drug in urinary infections; and various vitamin products.—(144) BURROUGHS WELLCOME AND CO. (Snow Hill-buildings, E.C.) had an illuminated stand where visitors might examine for themselves crystals of their 100 per cent. pure Insulin and Digoxin, the stable preparation of digitalis; they also showed a new product Ergometrine and their Tarrafax Brand Tannic Acid Jelly, Kepler cod-liver oil, and serological products.

(1) G. W. CARNRICK CO. (Brooks and Warburton Ltd., 232, Vauxhall Bridge-road, S.W.) exhibited their well-known glandular preparations Hormotone, Incretone, and Thelestrin, and introduced Pitrantrin, an anterior pituitary-like hormone.—(165) THOS. CHRISTY AND CO., LTD. (4/12, Old Swan-lane, E.C.), had on show a range of products, including Musterole Brand magnesia oil and mustard ointment; Estivin for hay-fever; Glycothymoline; and Lysoform disinfectant.—(13, 14) COATES AND COOPER LTD. (94, Clerkenwell-road, E.C.1), distributors for TEMMLER CHEMICAL WORKS, THE BIO-CHEMICAL LABORATORIES LTD., GOMENOL LABORATORIES, DESITIN WORKS, AMERICAN APOTHECARIES CO., CHEMICAL WORKS H. MACK NACHF., DR. JOACHIM WIERNIK & CO., A.G., DR. THILO & CO., MÜNCHEN CHEMICAL WORKS, and RUSSI & Co., in addition to the well-known products of these firms, introduced a new preparation of their own, Cerocol (colloidal cerium oxalate) for sea-sickness and air-sickness; and a new preparation by Russi and Co., Salepsil, intended to combine the sedative and hypnotic action of ethylphenylbarbituric acid with the antispasmodic action of valerian, the antivagal and hypocritic action of stramonium and of scopolamine, and the laxative effects of cascara sagrada; Mack's "Forapin" Bee Venom Salve for rheumatism; and the Ivago Brand Antipyrorrhæa Vaccine.—(3) CONTINENTAL LABORATORIES LTD. (30, Marsham-street, S.W.1), in addition to their Taxol, showed Crinex, a non-albuminous alcoholic preparation made from the follicular secretion of the ovary; and Antipeol, a vaccine filtrate containing the antiviral for staphylococcus, streptococcus, and pyocyanus.—(117, 118, 138) CROOKES LABORATORIES (Park Royal, N.W.10) picked out from their colloidal preparations Halycalcine, useful for emotional disturbances at the period and the menopause; Estroform, the new orthoformic preparation containing 50 per cent. alcohol for asthma and spasmodic cough; Mercury Sulphide for syphilis and psoriasis; Colsul aqueous, originally recommended for artificial pyrexia in general paralysis but now found useful in epilepsy also; a new range of transfusion solutions for giving large quantities of liquid intravenously, and a new preparation of aspirin, Collopyrin, put up in phials from which the label can be torn when they are given to a patient and which is marketed only to doctors.

(97) J. C. EXO LTD. (Pomeroystreet, S.E.) showed their well-known fruit salt.—(149, 150, 160) EVANS SONS LESCHER AND WEBB LTD. (56, Hanover-street, Liverpool) had a display of chemicals from which they selected for mention Colliron, colloidal iron containing 10 per cent. of iron and a minute trace of copper for massive iron therapy; diphtheria prophylactics in single and multiple doses; antitoxins of all kinds, and Hepatex I-M, solution of the liver fraction suitable for intramuscular injection, non-toxic and non-depressant.—(70) FASSETT AND

JOHNSON, LTD. (86, Clerkenwell-road, E.C.), drew attention to Otoferrin brand colloidal iron tonic; Zomite brand chloramine pessaries, a convenient non-greasy contraceptive and antiseptic; Burson Lastex yarn stockings; and the Seabury and Johnson series of dressings and plasters; and mentioned that Argyrol is now put up in tablets without a binder.—(10, 11) GENATOSAN LTD. (Loughborough), in addition to their well-known Sanatogen, Genasprin, Formamin, and detoxicated vaccines, had a new series of preparations called the Fissan Brand Products, incorporating an improved physical method of applying medicaments to the skin, in the form of powders, pastes, and lotion, and also anal ointment and suppositories.

(95, 96, 109) GLAXO LABORATORIES (56, Osnaburgh-street, N.W.) showed their popular food and vitamin products, and introduced Dissolved Vaccines, G.L., an entirely new vaccine preparation; it dissolves the bacteria and renders their products non-toxic without in any way impairing their capacity to produce antibodies.—(121) C. J. HEWLETT AND SON, LTD. (35/42, Charlotte-street, E.C.), had a number of original preparations on view, notably their Antiseptic Cream for eczema and abrasions; Coneuro, a nerve tonic; Heptagen, an aperient and cholagogue; Mist. Pepsinæ Co. c. Bismutho; Tannic Acid Jelly for burns; Fornalgar, a mouthwash and gargle; and Evapogens, a series of medicated skin lotions containing spirit.—(71) HOFFMANN-LA ROCHE CHEMICAL WORKS LTD. (51, Bowes-road, N.), in addition to Imadyl brand histamine, Prbstigmin, a peristaltic stimulant, also useful for relief of myasthenia gravis, and other well-known products, showed Larostidin, a histidine preparation for peptic ulceration; and Redoxon, synthetic vitamin C.

(86) HOUGH, HOSEASON AND CO., LTD. (2, Bridge-street, Manchester), had a range of products, including Tab. Arthritone for rheumatoid arthritis, and Tab. Eclectol Co., a combination of alkaloïds having a katalytic action on hormonal activity; and Formic glycerophosphates.—(45) HOWARDS AND SONS, LTD. (Ilford), showed their wide range of pure chemicals, especially stressing Quinisan, quinine bisalicylosalicylate for colds and influenza; their anæsthetic ether, carefully tested and purified; and had an exhibit showing the difference between the different densities of bismuth carbonate and the advantages of a light form for certain purposes.—(63) JOHNSON AND SONS (Hendon, N.W.) showed Estersal, a mixture of the ethyl and propyl esters of salicyl glycolic acid for the relief of rheumatic affections.—(166) KAYLENE LTD. (Waterloo-road, N.W.) had on view their preparations of colloidal kaolin, Kaylene-ol, Carbokaylene, and Kaylene Opaque Meal.—(119) LACTÉOL DU DR. BOUCARD (30, Rue Singer, Paris) showed their many preparations of lactic ferments, and Viatol, a vitamin tablet.—(29) WM. MARTINDALE (12, New Cavendish-street, W.) pointed out Calvitone, an assimilable calcium vitamin tonic with a cod-liver oil equivalent of 33 per cent.; and Sterules Iodo-Ray, a radiographic medium for pyelography and urography, a halogen derivative of hippuric acid in aqueous solution containing also dextrose to minimise the loss by solution into the tissues.

(148) MENLEY AND JAMES LTD. (64, Hatton-garden, E.C.), in addition to their Iodex, had two new preparations: Calsiod for rheumatic and arthritic conditions; and Benzredine inhaler, exhibiting greater potency than Ephedrine without irritation.—(103) H. R. NAPP LTD. (3 and 4, Clement's Inn, W.C.), among their many preparations, introduced Sedonan, a 5 per cent. solution of phenyldimethyl, pyrazolon, and anhydrous glycerin for the relief of inflammatory conditions in the ear; Ferro-Hepamult, a liver product in sugar-coated granules for anæmia; and Hepamult, their standardised liver extract, cheaper to use than fresh liver.—(120) OPPENHEIMER SON AND CO., LTD. (Handforth Laboratories, Clapham-road, S.W.), showed their Palatinoid and Bi Palatinoid products and various Alphidine compounds including the latest, Alphidine with guaiacum resin and sulphur precipitation, for rheu-

matic conditions.—(80) ORGANON LABORATORIES (1, Gordon-square, W.C.) had on view their Pregnyl, a gonadotropic hormone of pregnancy in a form which retains full activity over long periods; Menformon (Keto-hydroxyœstrin) in oily and aqueous solutions and vaginal suppositories; and Pernaemon Forte, a protein-free cod-liver extract of controlled hæmopoietic activity.—(73) Oxo LTD. (Thames House, Queen-street-place, E.C.), in addition to their well-known beef extracts and Lab-Lemco, a standardised extract for culture media, showed their Oxoid organo-therapeutical preparations, notably Hormonoxoid another pluriglandular tonic extract for injection; and Liveroid, Oxoid liver extract for injection, and Erythroid (desiccated gastric tissue) for anæmia.

(64) PARKE, DAVIS AND CO. (Beak-street, W.) selected from their range of products Antuitrin "Growth," a concentrated preparation of growth hormone from the anterior lobe of the pituitary gland, standardised on female rats; Gonococcus Soluble Toxin (Corbus-Ferry) grown in a special medium and used by intradermal injection; Staphylococcus Vaccoid, a mixture of staphylococcus toxoid and vaccine constituting a complete staphylococcal antigen; and Tuberculin P.P.D., tablets containing the purified protein derivative obtained from standard tuberculin by the method of Florence B. Seibert.—(75) PETROLAGAR LABORATORIES LTD. (Braydon-road, N.) had added to their Petrolagar compounds a pleasant non-bitter Petrolagar with Cascara, for those accustomed to doses of this drug; and Kaldrox, an emulsoid developed by activating colloidal kaolin with aluminium hydroxide gel, used for colitis, flatulence, and diarrhoea and in the treatment of peptic ulcer.—(99) PHARMACEUTICAL SPECIALITIES (MAY AND BAKER) LTD. (Dagenham, London) picked out for special mention Stellidin, a 4 per cent. histidine solution put up in ampoules for intramuscular injection for the ambulatory treatment of peptic ulcer; Sónalgin, a compound of soneryl and amidopyrin; Vinyl Ether, a new anæsthetic giving rapid and complete relaxation without sickness; and Ergometrine, a water-soluble, quick-acting alkaloid ergot given orally or intramuscularly.—(155) REED AND CARRICK (CANADA) LTD. (Distributors: Coates and Cooper Ltd., 94, Clerkenwell-road, E.C.), from among their range of endocrine products pointed out Nephritin, composed of cortex and convoluted tubules of the kidney; and introduced Tonicine, a new male and female gonadal tonic and restorative combined with strychnine and glycerophosphates.

(147) SANDOZ PRODUCTS (J. FLINT) (134, Wigmore-street, W.) among their many products had some new preparations, notably Bellergal, a compound of belladonna, Femergin and phenyl-ethyl-malonylurea for autonomic nervous disorders; they also pointed out the value of Femergin (ergotamine tartrate) for migraine; and Quinine-Calcium, intravenous and intramuscular injections, recommended for its preventive action against the penetration of toxins in acute infections.—(27, 28) SAVORY AND MOORE LTD. (143, New Bond-street, W.) showed their many products, including Medilax, a silver-coated vegetable pillule for constipation; Urotropal, their urinary antiseptic; and their Fructoles preparations, offering many medicaments in palatable solution; also Nembutal (Abbott) for short hypnotic and long sedative action, and Bromural (Knoll), a soporific.—(47) SCHERING LTD. (188-192, High Holborn, W.C.) selected from their range of medicinal products Progynon, for ovarian hypofunction; Proluton, corpus luteum hormone; Neotropin, a urinary antiseptic, to be combined with Cylotropin in obstinate cases, and their well-known Veramon, Medinal, and Uroselectan B.—(25a) SCOTT AND BOWNE LTD. (10, Stonecutter-street, E.C.) claimed for their Halivite cod-liver oil a vitamin potency of 1500 international A units and 200 international D units; and, in addition to the plain oil and pills, now make a malt and cod-liver oil extract for which they claim high potency.—(164) SHARP AND DOHME LTD. (76-78, City-road, E.C.), among their range of medi-

cements, pointed out that they were the first to introduce the single-dose treatment for diphtheria prophylaxis; they also showed their staphylococcus toxoid; Solution S.T. 37; and S.T. 37 Sucrets for mouth disinfection.—(153) TONICITY LABORATORIES, LTD. (20–24, Emerald-street, W.C.), showed their preparation Halmagon for administering the halogen compounds of magnesium.—(33, 34) WILLIAM R. WARNER AND Co., LTD. (300, Gray's Inn-road, W.C.), in addition to their Veganin, recommended for influenza, introduced Vince, a new antiseptic powder which in solution yields about 9.5 per cent. of nascent oxygen.

Foods, Drinks, and Vitamin Preparations

(135) ALLEN AND HANBURY'S LTD. (Bethnal Green, E.) showed their series of scientifically arranged foods for infants from birth to weaning, and their special half cream milk food, milk food with additional iron, whey, and cereal; also cod-liver oil, orange juice, and the combination in Haliborange.—(93) BOVril LTD. (148–166, Old-street, E.C.) showed their popular meat extract and stressed the Invalid form, devoid of seasoning, more highly concentrated, and with a greater albuminoid content.—(84) BRAND AND Co., LTD. (Mayfair Works, Vauxhall, S.W.), showed their pure raw meat juice; essences of beef and chicken; meat lozenges; and Brandox, preserved by a new method—the addition of malt extract instead of salt, which incidentally adds vitamins A, B, and D.—(100, 101) CADBURY BROTHERS LTD. (Bournville) once again dispensed heartening drinks of Bourn-vita and offered samples of their chocolate.—(46) CORN PRODUCTS Co., LTD. (Bush House, W.C.), showed their Dextrosol Brand Dextrose, identical with the sugar of the blood and tissues; and Karo syrup for infants and children, a mixture of non-irritating sugars in which the first digestive step has been accomplished.—(77, 78, 79) COW AND GATE LTD. (Cow and Gate House, Guildford, Surrey), in addition to their milk foods, displayed Frailac, a milk food with low fat and protein content for frail infants; Hemolac, a full cream milk food containing iron ammonium citrate; Lacidac, lactic acid milk powder, and especially Daltose C.G., a carbohydrate mixture containing maltose, dextrose, soluble dextrins, and vitamin D.—(115) ENERGEN FOODS Co., LTD. (Willesden, N.W.), had added to their Energen bread and other dietary preparations, Energen Cocoa, and a pleasant flavoured, unsweetened bramble jelly.—(163) GRANOSE FOODS LTD. (Watford) showed their dietetic foods, including Granose biscuits, consisting of pure wheat grain, and Granovita gluten bread for diabetes and obesity.—(72) HEUDEBERT DIETETIC PRODUCTS (Mount Pleasant, Alpertown, Middlesex) showed their many food products, especially those for diabetes, dyspepsia, obesity, and cardiovascular and hepatic disorders; and introduced Feculyse powder, a wheat-germ preparation flavoured with caffeine-free coffee, giving a diastase action very useful in cases of starch indigestion.—(108) HOVIS LTD. (London) had a display of the bread and cakes which can be made from their whole meal wheat flour containing vitamin B.—(112) INGRAM AND ROYLE LTD. (45, Belvedere-road, S.E.) showed the mineral waters for which they are agents, notably Vichy Célestins, Contrexéville-Pavillon, Karlsbad Water and Hunyadi Janos aperient water.—(49) KEEN, ROBINSON AND Co., LTD. (Carrow Works, Norwich), in addition to their Robinson patent barley and groats and Almata synthetic infant food, pointed out their mustard ointment, which can be applied directly as a poultice without any preparation, and their new Lemon Barley Water for the rapid preparation of a pleasant beverage.—(139) LEVER BROS. LTD. (Port Sunlight) showed their vitamin A and D products Essogen and Advita; Essogen is vitamin A, free from D, with a blue value of 2000, and Advita is A and D together, with an A value of 1250 and a D value of 1000 international units.

(146) THE MARMITE FOOD EXTRACT Co., LTD. (Walsingham House, Seething-lane, E.C.), presented

again their vitamin-B preparation and mentioned its anti-anæmic properties, the latest work on which has been incorporated in a new issue of their medical booklet.—(68, 69) NESTLÉ AND ANGLO-SWISS CONDENSED MILK Co. (6–8, Eastcheap, E.C.) showed their milk and cream preparations, and Lactogen dried milk in a new and attractive packing; and introduced Eledon, a dried buttermilk.—(50) PHILLIPS YEAST PRODUCTS LTD. (Park Royal-road, N.W.) had a stand to remind the medical profession of the value of live yeast in the treatment of many conditions, including anæmia, and pointed out that their preparation contains 1140 international units of vitamin B₁ per ounce.—(136) SISTER LAURA'S INFANT AND INVALID FOOD Co., LTD. (Springfield Works, Bishopbriggs, Glasgow), showed Sister Laura's preparation for rendering milk digestible; and Zomogen, a liquid restorative without metallic iron.—(126, 127, 128, 129, 130) TRUEFOOD LTD. (Bebington, Wirral, Cheshire) showed their humanised and full cream dried milks; and Secway, a whey preparation for premature infants and the treatment of digestive disorders.—(125) VIROL LTD. (Hanger-lane, Ealing, W.) attracted visitors by an illuminated graph showing the growth in weight of children on Virol, halibut-liver oil, and cod-liver oil respectively. The Virol growth corresponded almost exactly with the standard weight increase while the others fell below it. It was suggested that the cod-liver oil lacked protein and mineral salts and halibut-liver oil contained rather too much vitamin A for some children.—(85) VITAMINS LTD. (23, Upper Mall, W.) presented Bemax, the only vitamin food which is daily assayed by the Birch and Harris bradycardia method; and Fertitol oil of wheat germ for the administration of vitamin E.—(89) VITMAR LTD. (Southfields, S.W.) showed their well-known preparations and food for diabetes, obesity, and the Ketogenic diets, especially stressing their cheap, low-carbohydrate Health Bread for slimming and the treatment of indigestion.

Surgical Instruments and Appliances

(90) ALLEN AND HANBURY'S, LTD. (Bethnal Green, E.), had a large display of surgical instruments, appliances, and equipment, notably the St. Bartholomew's Hospital operation table with self-locking device for any position and lateral tilting movement, mounted on a new platform base which increases stability and enables the surgeon to sit; electrical instrument sterilisers of new design fitted with heat switch and automatic cut-out; A and H Azoule catgut mounted on eyeless needles; instruments for the treatment of fractures by various surgeons; suction pumps for producing negative and positive pressure; and Dr. Letterman's foot supports.—(7) ARMOUR AND Co., LTD. (Armour House, St. Martin's-le-Grand, E.C.), emphasised the value of their new sterilised surgical sutures on eyeless needles of carbon steel for causing the very minimum of trauma, and mentioned that all their sutures and ligatures are tested for sterility in the pathological department of a London hospital.—(30, 31) ARNOLD AND SONS (50–52, Wigmore-street, W.), from among their display of surgical instruments and tables, picked out a new transformer for use off main A.C. supply for light and cautery burners; a new blood drip apparatus used by Marriott and Kekwick; Minnett's gas and air apparatus for maternity cases; and Baron's antidote bag, containing suitable treatment for poisoning cases. They pointed out that the dressings prepared by John Bell and Croyden are now periodically tested by the Bland Sutton Institute.

(59) AURAL APPLIANCES LTD. (135, Wigmore-street, W.) demonstrated the latest improvements to their Sonotone hearing aids, which can now pick out sounds from all directions; and also a neat radio aid which enables the deaf to hear broadcasts through any set by bone conduction.—(52) BRITISH ALKALOIDS LTD. (Winchester House, E.C.) showed their anti-septic T.C.P., a combination of chlorine and iodine with phenol and benzoic acid.—(145) CLEMENT

CLARKE LTD. (16, Wigmore-street, W.) picked out from their optical apparatus the new Admiralty Diagnostic Set; the new Livingston Malingers and Phoria Test; the Fincham Coincidence Optometer, a small training instrument for convergence insufficiencies; and facial masks for disfigurements.—(141) STANLEY COX LTD. (11, Gerrard-street, W.) stressed their ultra short wave diathermy equipment with many improvements; and their cathode ray electrocardiograph with a much finer photographic tracing than has hitherto been obtained.—(167) H. E. CURTIS AND SON, LTD. (7, Mandeville-place, W.), showed their range of supports, notably the Curtis Belt and corset belt En Mains Croisées.—(33A) CUNSON, GERRARD AND CO., LTD. (Oldbury, Birmingham), introduced their new elastic plaster bandage Ceraban which is free from rubber and antiseptic and far less irritating than older preparations; also Peptavin, a nutrient tonic peptone wine.—(65) THE DENVER CHEMICAL MANUFACTURING Co. (London, N.W.9) reminded the profession of the value of antiphlogistine antiseptic poultice.—(53, 54) DOMEN BELTS Co., LTD. (67, Welbeck-street, W.), among their various pregnancy, gastropnoxis and general support belts, showed a new corset belt for heavy figures and those suffering from weak abdominal muscles: special ribbons running diagonally give resilience and supple support.

(8) DOWN BROS., LTD. (21 and 23, St. Thomas's-street, S.E.1), picked out from their comprehensive selection of instruments several surgeons' special instruments for open operations for fracture and for pin and Kirschner wire traction, and Ferris Smith's instruments for external ethmoid operation.—(154) J. AND E. FERRIS LTD. (33, Museum-street, W.C.) showed the latest improvements in their light, strong artificial limbs, made in exact counterpart of the good limb to avoid self-consciousness.—(18A) HARMAN FRESE (32, Great Dover-street, S.E.1) showed their well known range of contraceptive appliances, and remarked that the Gamophile, extra thin, 3-ply rubber occlusive pessaries were receiving warm welcome from the profession.—(26) BRUCE GREEN AND CO., LTD. (14, Bloomsbury-street, W.C.), showed electric ophthalmoscopes and retinoscopes, and a number of models of optical trial cases, spectacles, and lenses.—(18) THEODORE HAMBLIN LTD. (15, Wigmore-street, Cavendish-square, W.) had a range of spectacles and ophthalmic apparatus and inexpensive diagnostic sets. They showed the Dobson amblyopia reader, printed in red and black and used with a red filter to cut out the red letters; the spinal spectacles, for reading while lying flat; a pocket torch with focal illumination; and the rising front bifocal spectacles, which lift the reading part when required.

(4) HANOVIA LTD. (3, Victoria-street, S.W.) had on view a new Alpine Sun Lamp representing the major advance in this apparatus since 1905; it has a self-starting apparatus, is economical to work, and gives great actinic intensity at any angle.—(38) HAWKSLEY AND SONS, LTD. (83, Wigmore-street, W.), had a range of instruments for blood diagnosis, stethoscopes, microscopes, and baumanometers.—(17) HINDERS LTD. (174, Estcourt-road, S.W.6) had a stand showing metal supports, foot supports, and plaster bandages, and pointed out their latest extra light, inexpensive adjustable foot support, embracing the metatarsal dome; the Vigger bandage for supporting the ankle and instep; and their Hygiaplast, packed in airtight, drop-proof patent containers and supplied on master spools to which new rolls can be fitted when required.—(2) THE HOLBORN SURGICAL INSTRUMENT Co., LTD. (26, Thavies-inn, Holborn Circus, E.C.), had a display of surgical apparatus, operating tables, and chromium-plated steel consulting room furniture, and pointed out especially an electro-surgical hand motor for drills, burrs, and saws; the Holborn fitted obstetric case, and Vienna model vaginal hysterectomy instruments.—(143) JOHNSON AND JOHNSON (GREAT BRITAIN) LTD. (Slough, Bucks) showed

their plasters and dressings, including the Drybak waterproof adhesive plaster, and introduced the Ethicon new process catgut prepared in such a way as to ensure absolute uniformity, complete smoothness, and extreme pliability.—(142) C. DAVIS KEELER LTD. (47, Wigmore-street, W.) picked out from their ophthalmic display a new wide angle ophthalmoscope at a reduced price; and a new operating auriscope in which the lens has been set back from the ear-piece to allow room for manipulation.—(35) THE LONDON HOSPITAL LIGATURE DEPT. (Whitechapel, E.) exhibited their ligatures, pointing out that the London Hospital Ligature Laboratories is the only place in England where sterile surgical catgut is made throughout from the animal intestine to the sterile tube.—(137) J. F. MACFARLAN AND Co. (32, Bethnal Green-road, E.), in addition to their anæsthetic ether (Keith's) and chloroform, pointed out their Bissettes chloroform ampoules for the second stage of labour; and Opoidine soluble, injectable opium for premedication and insomnia.—(43) MEDICAL SURGICAL SUNDRIES LTD. (97, Swinderby-road, Wembley) exhibited medical and surgical sundries of all descriptions.

(92) MONSOL LTD. (Vincent House, Vincent-square, S.W.) pointed out the Monsol Gel, Neo-Monsol in jelly form in collapsible unbreakable tubes; the jelly mixes instantly with hot or cold water and can even be used without water. They also showed Monsola nasal compound in dropper bottles at a reduced price.—(57) PEARSON'S ANTISEPTIC Co., LTD. (172, Buckingham Palace-road, S.W.), had added to their Iodine-Medol ointment, Medol analgesic ointment, and Creolin disinfectant, the new Creolin Soap, a super-fatted germicidal soap for toilet or surgical use.—(24) W. H. PETTIFOR (11, Victoria-street, S.W.) had increased their range of hearing aids by a new electrical stethoscope for deaf doctors which can be used either as a stethoscope or as a hearing aid and can be worked with a loud-speaker if desired.—(42) PORTABLE X-RAYS LTD. (Power-road, Chiswick, W.) had an interesting stand showing X ray negatives taken under all kinds of conditions, demonstrating the great advance made in radiography at home.—(23) RAYNER AND KEELER LTD. (100, New Bond-street, W.) showed a range of ophthalmological instruments and spectacles and said that special interest was being taken in a narrow beam ophthalmoscope and a prism illuminated auriscope.—(51) RECKITT AND SONS, LTD. (40, Bedford-square, W.C.), showed their non-toxic, non-corrosive germicide Dettol to which they have now added, in deference to the wishes of dentists, Deftolin mouth wash and gargle, a combination of Dettol and aromatics.—(12) W. J. RENDELL LTD. (161-165, Rosebery-avenue, E.C.) had on view once more their contraceptive appliances.

(88) THE SCHOLL MFG. Co., LTD. (182, St. John-street, E.C.), showed their supports and remedies for the relief and correction of foot troubles of all kinds.—(62) A. G. SHELDON AND Co., LTD. (3, Great Woodstock-street, W.), showed their sterilised surgical dressings and stock outfits, and emphasised their day and night service in all departments.

(66) T. J. SMITH AND NEPHEW, LTD. (42, Tavistock-square, W.C.), have put up their popular Elastoplast dressings in a doctor's set containing 117 dressings of various sizes and types; they also have wound dressings—lint and gauze pads medicated with 5 per cent. bismuth subgallate on the Elastoplast base; and Cellona plaster-of-Paris bandages and Cellona splints.—(6) THE SURGICAL MANUFACTURING Co., LTD. (83, Mortimer-street, W.), had a display of instruments including a new series of rectal and vaginal specula with proximal lighting, and a new universal syringe for continual local anæsthetic injection, aspiration, infusion, transfusion, and pile injection.—(36A) EDWARD TAYLOR, LTD. (Monton, Lanes.), showing their wide range of medicated plasters, emphasised that their elastic adhesive is guaranteed not to cause irritation.—

(97) THERMOGENE CO., LTD. (160, Piccadilly, W.), in addition to their popular medicated wadding, emphasised the value of Thermogene Vapour Rub for rheumatism and headache.—(161) VICTOR X RAY CORPORATION LTD. (15-19, Cavendish-place, W.) specially pointed out among their apparatus the Inductotherm short-wave diathermy machine employing an entirely new principle—that of electro-magnetic induction—for heat generation in the tissues; this instrument generates an alternating current of 12,000,000 cycles per second and the only applicator required is the flexible insulated cable wound round the part to be treated.—(105) "WAITES" ANTI-SEPTIC LOCAL ANÆSTHETIC (Cook's Laboratories, New York) showed a new product; a local anæsthetic with Cobefrin, a new vaso-constrictor without epinephrin reactions, as well as their various anti-septic preparations and Solila steel needles.—(123) WATSON AND SONS (ELECTRO-MEDICAL) LTD. (Sunic-house, Parker-street, W.C.) selected from their X ray and light apparatus the Sunic consulting-room outfit which is compact, simple, and perfectly safe and can be supplied in portable form; the latest type of mercury-vapour apparatus; and examples of infra-red apparatus.—(16) THE WILSON RUBBER CO., LTD. (85, Buckingham-avenue, Slough), in addition to their range of rubber gloves and sleevelets, introduced a new post-mortem apron made of pure crêpe rubber, absolutely resistant to every risk of the mortuary.

PARLIAMENT

NOTES ON CURRENT TOPICS

Reassembly of Both Houses

BOTH Houses of Parliament reassembled on Tuesday, Oct. 22nd, having been summoned, a week earlier than had been arranged, under the power given to the Speaker and the Lord Chancellor at the instance of the Government by resolutions passed at the adjournment for the summer recess early in August last. The emergency power to call members of both Houses together at an earlier date was exercised for the purpose of a debate on the international situation.

Increased Children's Benefit

On Oct. 22nd Mr. ERNEST BROWN, Minister of Labour, announced an increase in the children's allowance under unemployment benefit from 2s. to 3s. This increase was recommended by the Unemployment Insurance Statutory Committee in July. The new rate will come into force on Nov. 8th.

HOUSE OF COMMONS

TUESDAY, OCT. 22ND

Ex-Service Men in Hospital

Sir IAN FRASER asked the Minister of Pensions if he had considered the hardship caused to the families of many pensioners who lost unemployment assistance under the Unemployment Acts on entering a Ministry hospital, with the result that their families may be obliged to have recourse to rate aid; and if he could see his way to remedy this grievance.—Mr. R. S. HUDSON (Minister of Pensions) replied: Yes, Sir. The hardship involved in some of these cases has been brought home to me in the course of my recent visits to Ministry hospitals. As hon. Members are aware, a pensioner who is in work when he enters hospital for an approved course of treatment can be granted under the Royal Warrant an allowance, in lieu of pension, to make up his loss of income. With the approval of my right hon. friend the Chancellor of the Exchequer, I propose in future to apply this principle broadly to the case of men who are in receipt of benefit or assistance under the Unemployment Acts before entering hospital, but who are not eligible for the standard allowance. The administrative details have still to be

worked out, but briefly it is intended to pay in these cases a supplementary grant, in addition to pension, which will, within the limits of the standard warrant allowances, make up the man's income from these statutory sources to what it was before or would otherwise be had he not entered hospital, allowance being made for reduced family expense by reason of the patient's maintenance in hospital, and for any health benefit which he may receive in lieu of his unemployment benefit. This concession will, I am satisfied, meet the grievance hitherto felt by the disabled ex-Service men in question.

Unemployment Regulations

Mr. GREENWOOD asked the Minister of Labour whether the inquiry into the Regulations made under Part II. of the Unemployment Act, 1934, had been completed; and, if so, whether he could indicate the measures the Government proposed to take.—Mr. E. BROWN (Minister of Labour) replied: I have had this matter under anxious and prolonged examination, in consultation with the Unemployment Assistance Board, and our inquiries are not yet completed. As the right hon. gentleman is well aware, the subject is one of great difficulty and complexity, and in view of the importance of a right decision, not only to the unemployed but in the whole fabric of our social life, it is essential that before new arrangements are submitted to Parliament for approval they should first be examined thoroughly from every standpoint. In these circumstances, it will not be possible to take any action immediately, and I do not anticipate that any alteration can be made in the existing position of the standstill arrangements before next spring at the earliest.

Births, Marriages, and Deaths

BIRTHS

- ALEXANDER.—On Oct. 17th, at a Glasgow nursing-home, the wife of J. R. B. Alexander, M.B. Glasg., Stormont, Galston, of a son.
 FARMER.—On Oct. 18th, at a nursing-home in Westcliff, the wife of A. Pring Farmer, M.B. Lond., Sudan Medical Service, of a daughter.
 HOLMES.—On Oct. 15th, at Paston, Peterborough, the wife of E. Arthur Holmes, M.R.C.S. Eng., of a daughter.
 MACLEOD.—On Oct. 18th, at St. Margaret's, Inverness, the wife of Dr. Alastair MacLeod, London, of a daughter.
 PEREGRINE.—On Oct. 11th, Dr. R. L. Peregrine, of Kessingland, near Lowestoft, of a daughter.
 PROWSE.—On Sept. 19th, at Ootacamund, South India, the wife of Dr. A. S. Prowse, Assam Oil Co., Ltd., of a daughter.

MARRIAGES

- ALDERTON—BLACKMAN.—On Oct. 12th, at Bexhill, R. Maitland Alderton, F.R.C.S. Eng., of Hadleigh, Suffolk, to Kathleen Blackman, of Bexhill.
 JEFFARES—DERBYSHIRE.—On Oct. 19th, at All Souls' Church, Langham-place, London, W., James Langley Maynard Jeffares, F.R.C.S. Edin., of Kegworth, to Katherine Mary, daughter of Mr. J. N. Derbyshire, of Rempstone Hall, Notts.

DEATHS

- CAMPBELL.—On Oct. 8th, at Cambridge, Massachusetts, Jessie Deans Rankin Campbell, M.B. Glasg., B.Sc., wife of Charles Macfie Campbell, M.D. Edin., of Harvard University.
 FOSTER.—On Oct. 13th, at University College Hospital, following an operation, George Muir Foster, M.R.C.S. Eng., of Hampstead, aged 65.
 GIBSON.—On Oct. 18th, at the hospital of Saint Nicholas, Pyrford, Surrey, John Monro Gibson, F.R.C.S. Eng., of Emsworth, Hants, aged 30.
 MAY.—On Oct. 16th, suddenly, George Francis May, M.D., C.M. McGill, L.S.A., late Medical Superintendent of the Durham County Mental Hospital.
 PLOWRIGHT.—On Oct. 16th, at North Wootton, King's Lynn, Charles Tertius Maclean Plowright, M.B. Camb.
 ROWSE.—On Oct. 13th, Edward Leopold Rouse, M.D. Brux., Lieut.-Colonel, R.A.M.C., T., of Putney and Harley-street, aged 67.
 WILLS.—On Oct. 15th, at Princes Risborough, Bucks, Alfred Wills, M.D. Lond., B.Sc., Hon. Captain R.A.M.C., aged 46 years.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ULVERSTON'S NEW HOSPITAL.—Plans for the new hospital at Ulverston, in Furness, are in preparation. It will provide 54 beds, including a maternity section and a children's ward. The estimated cost is £30,000, of which over £18,000 has already been received.

MEDICAL NEWS

University of Oxford

On Oct. 17th the degree of bachelor of medicine was conferred on R. E. Adam.

University of Cambridge

On Oct. 18th the following degrees were conferred:—

M.D.—B. F. Longbotham.
M.B., B.Chir.—E. M. Griffin.
M.B.—J. D. Hay, J. N. Groves, and C. G. Parsons.
B.Chir.—T. D. F. Money, *P. H. L. Playfair, R. I. N. Greaves, L. R. Gardner, E. P. H. Drake, J. H. Patterson, and W. F. Walton.

*By proxy.

Dr. G. H. F. Nuttall, F.R.S., emeritus professor of biology and director of the Molteno Institute, has been elected an honorary fellow of Christ's College.

University of Dublin

On Oct. 16th the degree of doctor of medicine was conferred on Simon Wigoder.

University of Glasgow

Mr. Edward Hindle, Sc.D., has been appointed regius professor of zoology in place of Prof. John Graham Kerr, who has resigned. Dr. Hindle has long been associated with medical work, notably in the investigation of yellow fever.

On Oct. 19th the following degrees were conferred:—

M.B., Ch.B.—Margaret D. Green, H. L. Campbell, and P. J. Cantor (with honours); R. M. Calder, James Cuthbert, I. D. Henderson, J. S. Hall, D. C. Miln, H. T. Richmond, Catherine Richardson, G. H. G. Hope, A. D. T. Govan, A. S. Rogen, Julius Levine, and J. B. Lynch (with commendation); John Aitken, May D. Anderson, Isaac Ashforth, A. Y. Barclay, R. J. W. Barlow, Harold Bernstein, J. C. Brash, D. R. Brown, P. M. H. Browning, I. W. Burke, J. F. Cadas, J. H. Chambers, J. H. C. Clarke, James Cochran, Julius Cohen, G. D. Cresswell, Maud G. Dempster, R. I. T. Dunnachie, D. J. Easton, J. C. Eaton, P. F. Fletcher, Audrey M. Forbes, Kenneth Fraser, Max Freedman, W. G. Garrow, G. McL. Gorrie, R. J. Gourlay, Ronald Gowns, William Gray, Henry Greer, A. W. St. C. Greig, J. F. K. Grieve, G. H. Hall, Mary D. Hardie, G. A. E. Harman, J. W. Henderson, John Hilferty, W. C. Howie, H. E. Hutchison, Charles Kelly, W. McK. S. Kelso, A. S. M. King, G. B. L. Laird, William Laurie, James Leckie, William Leslie, D. S. MacL. MacArthur, Patrick MacArthur, Elizabeth McC. McCann, W. M. McCutcheon, R. S. McGeorge, G. A. Macgregor, J. S. McGregor, William McKechnie, William MacKendrick, Norman Mackenzie, C. J. Mackinlay, Angus Macleod, J. D. McRae, William Magauran, J. B. Mair, S. L. Mann, R. D. Menzies, J. S. Meredith, H. H. Miller, Archibald Morrison, H. A. Mullen, E. H. Murchison, D. A. Naismith, Folarin Ogunro, D. B. Ramsay, William Richmond, Jacob Schloss, D. G. Smith, F. A. Smith, David Stephenson, J. E. Struthers, Janet W. Sutherland, George Swan, J. F. Swan, J. R. Taylor, Donald Thomson, J. E. Tillotson, James Watt, W. J. Weetch, J. H. Werk, T. C. B. Williamson, R. W. Wyse, R. P. Young, and W. C. Young.

The Brunton memorial prize and the West of Scotland R.A.M.C. memorial prize were awarded to Margaret D. Green.

Royal College of Surgeons of Edinburgh

At the annual meeting of the College held on Oct. 16th the following office-bearers were elected for the ensuing year: president, Mr. Henry Wade; vice-president, Dr. A. H. H. Sinclair; secretary and treasurer, Mr. J. W. Struthers; members of president's council, Mr. W. J. Stuart, Dr. J. S. Fraser, Mr. J. M. Graham, Prof. R. W. Johnstone, Prof. D. P. D. Wilkie, and Mr. J. J. M. Shaw; representative on the General Medical Council, Mr. Alex. Miles; convener of museum committee, Dr. A. Logan Turner; and librarian, Mr. D. M. Greig.

The following candidates who have passed the requisite examinations were admitted to the fellowship:—

U. P. Sinha, M.R.C.S. Eng.; E. W. B. Griffiths, M.B. N.Z.; G. N. Barker, M.B. Lond.; E. F. Barnardo, M.B. Lond. A. G. Bester, M.B. Cape Town; D. G. W. Brown, M.B. Liverpool; R. C. Burr, M.D. Ontario; H. P. Clark, M.D. Manitoba; P. F. S. Court, M.R.C.S. Eng.; H. D. Cronyn, M.R.C.S. Eng.; John Durran, M.B. Edin.; T. G. H. Hogg, M.B. Melb.; Christopher Hotson, M.B. Edin.; Daniel Hugo, M.B. Dub.; R. J. Kellar, M.B. Edin.; M. N. Khanna, M.B. Punjab; A. L. McFarlane, M.R.C.S. Eng.; W. A. Mackay, M.B. Glasg.; N. J. L. Margaretson, M.D. Ontario; A. G. G. McVillie, M.B. Edin.; Jack Penn, M.B. Witwatersrand; L. W. Plewes, M.D. Toronto; Allen M. S. Pollock, M.R.C.S. Eng.; Thomas Purce, M.B. Belf.; T. R. Quinn, M.B. Sydney; A. C. Rifer, M.B. Lond.; A. L. Sheld, M.B. N.Z.; George Stephen, M.B. Aberd.; and Dr. R. L. Stevenson, M.B. N.Z.

Royal Sanitary Institute

Dr. M. T. Morgan, medical officer of the Ministry of Health, will deliver the Benjamin Ward Richardson lecture at the institute (90, Buckingham Palace-road, London, S.W.), on Tuesday, Nov. 12th, at 5.30 p.m. His subject will be some details of the system of health inspection of meat and meat products destined for export, in the great abattoirs of South America. Sir Arthur Newsholme will preside.

West Riding Association of Graduates of the University of Edinburgh

This association is holding its annual general meeting at the Midland Hotel, Bradford, on Nov. 6th at 6.45 p.m. The annual dinner will take place at 7.30 p.m., and the guest of the evening will be Mr. Henry Wade. Further information may be obtained from the hon. sec., 4, Clifton Villas, Bradford, Yorks.

Post-graduate Teaching in Glasgow

The Glasgow Post-Graduate Medical Association has arranged for a series of lectures and clinical demonstrations for practitioners to be given on Wednesday afternoons from Nov. 6th to May 27th at 4.15 p.m. Special courses in ophthalmology, obstetrics, radium therapy, and diseases of the ear, nose, and throat will also be held during the session. The secretary may be addressed at 9, Woodside-terrace, Glasgow, C.3.

London Hospital Dinner

Prof. H. M. Turnbull presided over the annual dinner held at the Trocadero Restaurant on Oct. 17th, and the 309 diners included 64 of his former pathology assistants, concentrated at a central table. Before there were any speeches Prof. Turnbull took wine with them, and received a first instalment of the musical honours which were later accorded by the whole room. After speaking of the events of the hospital year, which has seen an entry of students unequalled since 1906, he drew a comparison between present conditions and those when he came to the London—when members of the staff, springing out of their broughams and victorias, were distinguishable from students, and (in the absence of morbid anatomists) buried their own dead. In a man of his temperament, he said, to whom everything at times seemed futile, it was always a great comfort to have young people around: the young gave far more than they ever received. His own work would have been given up without Robert Worthington, and no man in any walk of life had ever had a more faithful and altruistic assistant than W. W. Woods. There had also been women assistants in the department, and he was very proud of them. It was sometimes said that the presence of women would spoil a hospital dinner. But why? Any woman who had worked in a pathological laboratory was likely to know what passed for wit among men—Dr. Charles Miller, proposing the chairman's health, said it was half in jest that long ago L. A. Smith described Turnbull's department as the palace of truth, but this was exactly what it had become. He recalled that Turnbull, after his distinguished career at Oxford had won a cup on the Cresta run and studied in foreign schools before coming back to building up the foremost pathological institute in this country. Besides raising a school of morbid anatomists he had taken an interest in every student who came under him, so that his name was one which inspired pride, gratitude, and affection.

Various speakers then rose in response to popular demand. Dr. Woods confined himself to two words; Dr. Lewis Smith said that the old clinicians, almost bankrupt alike in money and ideas, had covered their deficiencies magnificently; Sir James Walton said there was no other hospital where clinicians received the same ungrudging help they got from Prof. Turnbull's department; Mr. Russell Howard, Mr. Hugh Lett, and Mr. James Sherren (returning to the dinner after ten years) made lively contributions to the entertainment; Mr. McNeill Love contrived to acknowledge his golf cup with an apt tribute to Prof. Turnbull's training; and Mr. Neligan, encouraged by Sir William Goschen, said a few well-chosen words on behalf of himself and Mr. Lindsay as organisers of the dinner. The survivors then went home.

Society for the Provision of Birth Control Clinics

A lecture on the theory and practice of contraception will be given to medical students and practitioners by Dr. Gladys Cox on Friday, Nov. 15th, at 6 P.M., at the Walworth Women's Welfare Centre, 153A, East-street, London, S.E. Practical demonstrations will be given at 6 P.M. and 7 P.M. on Nov. 22nd and 29th. Further information may be had from the secretary at the clinic.

Tribute to Dr. D. A. Coles

On his retirement from the chairmanship of the advisory medical committee of the Industrial Welfare Society and of the Council of Industrial Medicine, Dr. D. A. Coles, with Mrs. Coles, was entertained to dinner at the Goring Hotel, London, on Oct. 15th. Prof. E. L. Collis presided, and a letter was read from the Duke of York, president of the society, paying a warm tribute to the work accomplished by Dr. Coles. Letters expressing appreciation of all he had done in promoting international congresses of doctors were received from Dr. C. J. Mijlief (International Association for Life Saving and First Aid to the Injured), Dr. C. Yersin (Swiss Medical Society for Industrial Accidents and Diseases), and Dr. Langelez (International Congress for Accidents and Industrial Diseases). A cable from Dr. H. H. Kessler (Newark, U.S.A.) on behalf of the American members of the International Congress of Industrial Accidents and Diseases was also read. Short speeches were delivered by Dr. Margaret Dobbie-Bateman, Dr. Edward Burnet, Dr. Gilbert Burnet, Mr. Robert Hyde, and Dr. T. E. A. Stowell. In expressing his thanks, Dr. Coles congratulated Dr. Stowell on his appointment as chairman of the advisory medical committee, and the members on having secured one so eminently fitted for the post.

Fellowship of Medicine and Post-Graduate Medical Association

The following all-day courses are to be given: chest diseases, at the Victoria Park Hospital (Oct. 28th to Nov. 2nd); urology, at St. Peter's Hospital (Nov. 4th to 16th); and medicine, surgery, and gynaecology, at the Royal Waterloo Hospital (Nov. 11th to 23rd). Afternoon courses will be held as follows: venereal diseases, at the London Lock Hospital (Nov. 18th to Dec. 14th); infants' diseases, at the Infants Hospital (Nov. 25th to Dec. 7th). A week-end course in clinical surgery will be given at the Royal Albert Dock Hospital (Nov. 2nd and 3rd); and in gynaecology at the Samaritan Hospital (Nov. 15th and 16th). On Nov. 7th Dr. Norman Haire will lecture on practical contraception at 4 P.M. at the Medical Society of London. Dr. Gardiner-Hill's lecture on thyroid in the endocrinology series which was postponed will be given on Tuesday, Oct. 29th, at 8.30 P.M. at the National Temperance Hospital. A clinical and pathology course for M.R.C.P. candidates will be held on Tuesdays and Thursdays, from Nov. 26th to Dec. 12th, at 8 P.M. at the National Temperance Hospital. The courses and lectures are open only to members and associates of the fellowship. The secretary of the Fellowship may be addressed at 1, Wimpole-street, London, W.1.

Research at Maudsley Hospital

At its meeting on Oct. 22nd the London County Council accepted the offer of the Rockefeller Foundation to contribute £9000 to be expended on psychiatric research at the Maudsley Hospital, Denmark Hill, over a period of three years at the rate of £3000 annually. It has been agreed that the grant from the Foundation shall be used as salaries for five research workers to be nominated by the medical superintendent of the hospital and the director of the central pathological laboratory. For the present two of these posts are to be held by workers engaged on clinical investigations which will be carried out mainly in the hospital, and Dr. W. Mayer Gross, formerly professor at the University of Heidelberg, and Dr. Erich Guttmann, formerly privatdozent at the University of Breslau, have been appointed. The other three workers will be engaged in pathological research, mainly in the laboratory, and Dr. Alfred Meyer, formerly professor at the University of Bonn, Dr. Adolf Beck, formerly assistant at the Institute of Hygiene and Bacteriology of the University of Marburg, and Mr. Grey Walter, B.Sc., formerly research assistant at the pathological laboratories, Cambridge, have been appointed.

Vacancies

For further information refer to the advertisement columns

- Accrington, Victoria Hospital.—H.S. £150.
 Bagshot Rural District Council, &c.—M.O.H., &c. £1000.
 Belgrave Hospital for Children, Clapham-road, S.W.—H.S. At rate of £100.
 Birmingham City.—Asst. M.O. for Maternity and Child Welfare. £500.
 Birmingham United Hospital.—Res. Anaesthetists for General Practice, respectively.
 Birkbeck Hospital, Birkbeck, W.—H.S. At rate of £135.
 Bristol County Mental Hospital, Haywards Heath.—Asst. M.O. £350.
 Bristol Eye Hospital.—Jun. Res. H.S. £100.
 Bristol, Ham Green Hospital and Sanatorium.—Jun. Asst. Res. M.O. £250.
 Chesterfield Poor Law Institution and Infirmary.—Res. M.O. £150.
 Dreadnought Hospital, Greenwich.—Anaesthetist. 50 guineas.
 Dundee Royal Infirmary.—Hon. Asst. Visiting Surgeon.
 East Ham Memorial Hospital, Sharnbury-road, E.—Hon. Physician.
 Finsbury Dispensary, Breaver-street, E.C.—Res. and Asst. Res. M.O.'s. £250 and £200 respectively.
 Folkestone, Royal Victoria Hospital.—Jun. Res. M.O. At rate of £150.
 General Lying-in Hospital, York-road, Lambeth, S.E.—Jun. Res. M.O. and Anaesthetist. At rate of £100.
 Halifax General Hospital.—Jun. Res. M.O. £250.
 Hastings, Royal East Sussex Hospital.—Asst. Pathologist. £300.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Asst. Physician. Also Hon. Asst. Surgeon.
 Host of St. Luke, 14, Fitzroy-square, W.—Res. M.O. At rate of £200.
 Hore General Hospital.—Hon. Physician. Also Hon. Asst. Anaesthetist.
 Huddersfield Royal Infirmary.—H.S. for Eye, Ear, and Obstet. Depts. At rate of £150.
 Leeds, Killingbeck Sanatorium.—Sen. Asst. Res. M.O. £350.
 Leicester Royal Infirmary.—Jun. Res. Anaesthetist. At rate of £150.
 L.C.C.—Temporary District M.O.'s for Special Areas. £100-£235.
 Liverpool, Smithdown-road Hospital.—Sen. Res. Asst. M.O. £350.
 London Homoeopathic Hospital, Great Ormond-street, W.C.—Gynaecological H.S. At rate of £100.
 London Hospital, E.—Surgical 1st Asst. and Reg. £300.
 Manchester City.—Asst. Tuberc. O. £650.
 Maudsley Hospital, Denmark Hill, S.E.—2nd Asst. M.O. At rate of £625.
 Metropolitan Ear, Nose, and Throat Hospital, 2, Fitzroy-square, W.—Asst. Surgeon and Sen. Clin. Asst.
 Newcastle-upon-Tyne, City Hospital for Infectious Diseases.—Res. Med. Asst. £250.
 Newport, Mon., Royal Gwent Hospital.—H.S. At rate of £135.
 Oldham Royal Infirmary.—Cas. O. and H.P. At rate of £175.
 Prince of Wales's General Hospital, N.—Hon. Physician to Dept. of Physical Medicine.
 Princess Louise Kensington Hospital for Children, St. Quinton-avenue, W.—Hon. Asst. Physician.
 Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. M.O. for Isolation Hospital. At rate of £200. Res. Anaesthetist. At rate of £100. Res. Anaesthetist and Dist. Res. M.O. At rate of £90. Also Asst. Res. M.O. At rate of £80.
 Queen's Hospital for Children, Hackney, E.—Dermatologist.
 Rotherham Hospital.—H.P. £180.
 Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.
 Royal College of Physicians, Pall Mall East, S.W.—Leverhulme Research Scholarship. £500.
 Royal Free Hospital, Gray's Inn-road, W.C.—Anaesthetic Registrar. £100. Also Dermatologist.
 St. Helens Hospital, Lanes.—Jun. H.S. £150.
 St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—Part-time Radiologist. At rate of £125.
 St. Thomas's Hospital, S.E.—Ophthalmic Surgeon.
 Sheffield Jessop Hospital for Women.—Asst. Hon. Surgeon.
 Sheffield, Winter-street Hospital.—Asst. Tuberc. O. £350.
 Southend Municipal Hospital.—Asst. M.O. for Rochford Municipal Hospital. £350.
 Southend-on-Sea General Hospital.—Hon. Physician for Charge of Physical Medicine Dept.
 South London Hospital for Women, Clapham Common, S.W.—Clin. Assts. for Gynaecological Out-patients.
 Wakefield, Scarboro Park Mental Hospital.—Asst. M.O. £650.
 West Bromwich County Borough.—M.O.H. and School M.O. £1000.
 West London Hospital, Hammersmith-road, W.—Res. Cas. O. At rate of £100.
 Wimbledon Hospital, Thurstan-road, S.W.—Res. M.O. At rate of £150.
 Woolwich and District War Memorial Hospital, Shooters Hill, S.E.—Two H.S.'s. Each at rate of £100.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Marlow (Bucks) and Medbourne (Leicester).

NOTES, COMMENTS, AND ABSTRACTS

CHANGING SURGERY *

By GEORGE E. GASK, C.M.G., D.S.O., F.R.C.S. Eng.
EMERITUS PROFESSOR OF SURGERY IN LONDON UNIVERSITY

You may think that this title presages a comparison between the results of aseptic surgery and those before Lister. My object however is to look at the present rather than the past, and the changes of which I shall speak are those of the last 30 years. Looking back over this period one realises that there are many events of great importance which might be recorded—e.g., the consolidation of the gains of sepsis over anti-sepsis, resulting in the evolution of a nearly perfect technique; or the revolution following the application of X rays to diagnosis. Great, however, as these innovations may be, it will be agreed, I think, on reflexion that the greatest and the most far-reaching in its effects is the growth of specialism, by which is meant the segregation of patients suffering from like diseases and their treatment by doctors who devote themselves to one special line of study. Specialism is a compelling force which brings many changes in its train. Not only has it altered the type and scope of surgery, but it has greatly affected, and is still affecting, the development and administration of our hospitals and medical services.

BIRTH OF SPECIALISM

No single date can be given to mark the birth of specialism. For centuries past there have been men, often with hereditary training, who gained their living by cutting for stone or couching for cataract. St. Barts' had specialists of a sort in the sixteenth century and even female practitioners, for in 1554 Elizabeth Hall was paid three shillings for curing the scald head of a certain John Turner. Until the middle of the nineteenth century the physicians and surgeons undertook to teach and practise every branch of their art saving midwifery. About that time the need for specialism seems to have arisen, or at all events the cry for some special teaching, for in 1867 Dr. James Andrew and Dr. Reginald Southey were appointed demonstrators in dermatology, although there was still no special clinic. Three years later the governors set up special departments for diseases of the eye, of the ear, and of the skin. Special times were fixed for seeing the patients but the medical officer in charge remained a general physician or surgeon. Thus in 1870 Dr. Samuel Gee, then an assistant physician, was put in charge of the dermatological department. What he thought of specialism then is summed up in his remark "There is a name that I hate, nay there are two names that my soul abhorreth, the name of a specialist and the name of a consultant." In a few years came the inevitable demand that the officers in charge should be specialists and provided with beds and all the accessory facilities for carrying on their special work. These demands were met, often, it must be admitted, in a grudging manner and we have the special departments much as we know them to-day.

In the early years of the present century the tide of specialism swept on resistlessly, and it looked as if soon there would be no place for the general surgeon. Surgery threatened to divide into numerous branches, so that now we have proctologists and urologists, surgeons for the brain, the eye, the nose,

the ear, as well as radiologists, cardiologists, gastrologists, and many others. This change is not confined to any one country; it has spread over the whole world, although it has reached its height in America where there is hardly an organ or a special function of the body to which a specialist is not attached.

My own feeling is that specialism is the direct and natural outcome of the growth of the natural sciences and their application to medicine. The latter half of the nineteenth century witnessed a tremendous outburst of scientific work; new discoveries came one after another—electricity, X rays, wireless, radium—in quick succession. Modern medicine makes use of almost every branch of natural science. Physics, chemistry, biology, mechanics, electricity, radiology, optics, and many others bring to medicine instruments of precision for diagnosis, for detailed examination, or for treatment. Take one example. Consider the effect of the discovery of the reflecting mirror. It has illumined the darkest recesses of the body; it has given us the ophthalmoscope, the laryngoscope, and the cystoscope; it has thrown a revealing light on many hidden mysteries. Thus medicine has become so big a subject, the number of facts to be remembered so great, that man's mind cannot grasp them all at once, with their meaning and application. He has been forced to devote his attention to a more limited field. This is the main reason for the rise in specialism.

As a result of this increased knowledge the practice and outlook of the surgeon has changed. It is no longer possible for the frock-coated surgeon to walk round his wards and make a correct diagnosis with a shrewd glance of his trained eye. I remember a distinguished surgeon of the last century when shown a section under the microscope saying "I do not know anything about this microscope, but I do know that that man has a sarcoma because I have seen one before." The modern surgeon in his white coat has to know a great deal more than his Victorian ancestor. He must have a thorough mastery of surgical technique, but he needs also a sound working knowledge of physics, chemistry, and other sciences. Take a case of urinary disease. A complete examination involves, in addition to a routine overhaul of the patient, an inspection of the interior of the bladder with a cystoscope, a pyelogram of the ureters and renal pelvis, a bacteriological examination of the urine, and an estimate of the excretory efficiency of the kidneys by a chemical analysis. The whole examination is a lengthy and complicated process involving an accurate knowledge of a number of scientific methods. It is easy to understand how it has become necessary for men to limit the scope of their work and to devote themselves to special subjects.

But though it has been found desirable that for a certain time special subjects should be taught and studied by special men, it is not necessary to believe that specialised work must always continue to be segregated from general surgery in the manner and to the extent in which it is done to-day. Some of the specialties as they become better known and their methods standardised will come back to general surgery. We see this occurring at the present time. Our young men are learning to use the cystoscope as they learn to drive a motor-car. When they become senior, they will need no cystoscopist.

Medical teaching has not given all the help to medical students that it might have done. There

* Abstract of presidential address to the Medical Society of London on Oct. 21st, 1935.

seems hope that this lack may shortly be remedied and that the syllabus of basic sciences will be so framed as to include many of the subjects which are of special interest to medical men, the curriculum becoming more harmonious and better designed to meet the growing demands of modern medicine. If the plan is successful the doctor of to-morrow will be better equipped to deal with the multitudinous applications of science. There will then be less need for the cleavage of surgery into special subjects.

DEVELOPMENT OF THE TEAM

One result of this rapid increase in scientific knowledge, and the difficulty of one man doing everything very well, is the development of the team spirit. This is of recent growth and is largely a phenomenon of the Great War and of post-war surgery. It was seen at its height in casualty clearing stations during the years 1917-18 where machinery was gradually evolved for the rapid and efficient treatment of enormous numbers of wounded. Here in the reception-rooms the patients were examined, diagnosed, and distributed to various sections where other teams took care of them for treatment and disposal. Various types of injuries—head, chest, fractured femurs—were segregated in special hospitals. War surgery became team-work because it was economical in time and more efficient.

But long before the war the Mayo Clinic was drawing visitors to Rochester, Minn., from the world over. The secret of the success of William and Charles Mayo was the development of the team spirit on a gigantic scale. In 1929 the team consisted of some 195 physicians with an army of assistants and technicians. The clinic is often belittled by those who have never visited it. It has been described as mechanisation of medicine or surgery run on the factory belt. It is true that in this clinic a patient has to go through a number of departments; but it is also true that many of the routine examinations, such as blood and urine analysis, which are necessary parts of every investigation, can be done more economically by non-medical technicians than by qualified doctors. The use of technicians has been developed to the nth degree at the Mayo Clinic; we are beginning to do it here—but very very slowly. Another advantage is the avoidance of dissipated energy. The doctors do not waste their time running from one end of the city to the other. A millionaire in one of the Southern States once wrote to Mayo asking him to visit him, to which Mayo replied that if the millionaire wished to see him he must come to Rochester. The millionaire telegraphed "Come at once, money no object." To this the answer flashed back "Money no object, not coming." The type of work in the Mayo Clinic is not essentially different from that done in all serious European hospitals, only in these it is done in a minor way and less efficiently. The Mayos are the owners and dictators of their hospital, they can do as they like with the money they earn; our hospitals are governed by cumbrous machinery, the legacy of monastic or conventual ancestry.

THE UNIT SYSTEM

Another change since the war is the formation of medical and surgical units. These are essentially teams of workers under the direction of a whole-time physician or surgeon who is relieved of the cares of private practice. The underlying idea is sound and in harmony with the spirit of the age. It combines the team spirit with improved organisation without interfering with the practice of bringing the medical

student into intimate contact with the patients. It is an attempt to graft on our well-tried and peculiarly English system a means whereby clinical education may be placed on a more scientific basis. In my opinion the greatest hindrance to our surgical work in this country is lack of organisation and want of sufficient assistants, both medical and technical. The units have done something to remedy this lack, but they themselves have suffered from it. See what is happening to-day in our London hospitals. A few years ago a surgical firm generally consisted of a surgeon, an assistant surgeon, and one or two house surgeons. Most of the surgical services have now added an extra man, commonly called a chief assistant. Not so long back hospital governors considered it the duty of the surgeons to do all the operations. Now it is being realised that the routine operative work can be done as well by the young men, leaving more time for the seniors to do progressive work. Moreover, the performance of routine operative work is valuable training in technique for the younger men, an opportunity which was largely absent when men of my generation held junior posts. Another advantage of this increase in operative personnel is the avoidance of long lists and long operating days which tired out all concerned and led to the rough technique which at one time (according to foreigners) characterised London surgery. This is a beginning but it is not enough. With more assistance, both medical and technical, more organisation would be possible, with better work and quicker returns. The only obstacle is financial. Good surgery, like most other good things, costs money.

EFFECTS OF THESE CHANGES ON THE CHARACTER OF SURGERY

How are these changes affecting the nature of the surgery which is being done. If one compares the operation lists of the present day with those of 30 years ago, one sees that surgery has become more preservative and less excisional. The tendency to say "this structure is diseased let us cut it out" is giving place to an attempt to preserve it. How Seldom now does the surgeon spend hours dissecting out tuberculous lymphatic glands of the neck; rational treatment combined with the removal of focal sepsis has rendered this unnecessary. To take another instance, think how gastrectomy for gastric ulcer, an operation so much in vogue ten years ago, is giving way to conservative means. A few years ago, while visiting a foreign clinic, we were shown—with some pride—a cupboard in which were suspended about a hundred stomachs. It reminded me of a gamekeeper's larder. I suppose in each case some forty or fifty square inches of stomach had been removed in order to cure an ulcer about half an inch in width. A triumph of technique and a tribute to the operative skill of the surgeon but not to his common sense. I hasten to add that gastrectomy is at times beneficial, but it is the failure of remedial treatment which makes it necessary.

In urinary surgery the use of the cystoscope, of biochemical tests to ascertain renal efficiency, and the application of radiography have revolutionised our surgery and have helped to preserve many kidneys which formerly would have been excised. The enlarged prostate still remains a riddle awaiting solution. The mortality from prostatectomy has certainly been reduced but it is still too high. The work of Prof. Kennaway and his team suggests that an endocrine secretion may in time furnish a means of avoiding operation. It seems almost a paradox

that the chief aim of the surgeon should be to find ways of avoiding surgery; but that is as it should be, for the best surgeon is an operating physician.

In neuro-surgery there is a growing tendency for the surgeon undertaking operations on the brain and spinal cord to make his own examination of the patient and to make his own diagnosis. He is no longer content to act the plumber for the physician, and this is a healthy tendency. Similar changes are to be seen in the surgery of the chest. The thoracic surgeon is expert in the use of the stethoscope, the bronchoscope, and all the resources of radiology. He makes his own diagnosis and as a result a technique has been evolved by which a diseased lobe of the lung can be excised with safety. This may, one hopes, be a step towards the better understanding of the cause and prevention of disease that will lead to preservation rather than extirpation. In both these branches we see a type of specialism of which the exponents are at the same time physicians and surgeons. They are not so much thoracic surgeons or neuro-surgeons as specialists in diseases of the chest or in diseases of the nervous system. This is all to the good; for the separation of surgery from medicine, a legacy of the Middle Ages, has been the most dreadful obstacle in progress and we have not recovered from it yet. Is it too much to hope that before long the director of a unit will have the supervision and direction of both the medical and surgical sides?

A further change which has come to surgery is the use of radiation both for diagnosis and treatment. The radiographic department has become an essential part—and incidentally a very expensive part—of every hospital in every town. Radiation for curative purposes has not yet found its level. The use of radium in the treatment of cancer has not proved a universal panacea, but radium has supplanted excision for superficial growths of the skin, and it is the method of choice for the treatment of epithelioma of the tongue and mouth. The old and terribly mutilating operations about the mouth and jaw are now rarely necessary. Research in teletherapy with massive doses of radium and high-powered X ray installations is being carried on and we wait, with some impatience, for further information.

Knowledge of the anatomy and physiology of the sympathetic nervous system is leading to the performance of new operations, such as that for Raynaud's disease. Arteriography throws light on the permeability of diseased arteries. But enough has now been said to support my contention that the application of the fundamental sciences to medicine has led to profound changes in the type of surgery which is being done.

EXPERIMENTAL SURGERY

There is a very recent growth, the importance of which it is difficult to exaggerate. A purist might say that institutions for experimental surgery are merely specialised physiological laboratories and in a sense he would be correct, for advance in surgery now is largely along physiological lines. But these experimental stations are directed immediately towards solving some of the many problems which confront the surgeon daily in his work. The laboratories of the surgical unit at Edinburgh under the guidance of Prof. D. P. D. Wilkie have already produced some stimulating work. And now, owing to the far-sighted generosity of Sir Buckston Browne, the Royal College of Surgeons of England has come into possession of a research farm at Downe where

Sir Arthur Keith is master and Dr. John Beattie director of research. Here indeed is an indication of the spirit of the times. The conservator of the museum now combines with that office the duties of director of research; maintenance of the museum, valuable and essential as it is, no longer marks the limits of the College's activities. Young surgeons are to have the chance of doing surgical research at a time when their minds are plastic and fertile. The *British Journal of Surgery* has decided to devote a section to the publication of this research work.

SOCIO-POLITICAL CHANGES

Walter Fletcher once remarked that the two greatest benefactors to British medicine were King Henry VIII. and Mr. Lloyd George: the one for abolishing the mediæval monasteries and laying the foundations of modern hospitals, the other for giving England the insurance system. Many of us can remember the storm of indignation which followed the introduction of the panel system and the bitter vituperation which was hurled at the head of the prime mover. Now the panel is a part of English life, and in the view of most it has proved of substantial benefit to British medicine. To my mind its great advantage lies in the fact that it has so raised the standard of living among doctors that men with a higher standard of education and consequently capable of better work are coming into the profession. For evidence of this see an article on Present-day Openings of Medical Practice in *THE LANCET* of August 31st. The great lack of the panel system was that no institutional treatment was provided; examination and medicine but no hospitals.

This lack is now to be remedied by the results of the Local Government Act, 1929. How quietly this Act came into being compared with the storm which ushered in the panel system; and yet its influence on the health and well-being of the people will be far greater, and incidentally it will influence the quantity and character of the surgery that is done. This Act has transferred the responsibility of the care of the sick poor from the poor-law to the municipal authorities. Thirty years ago one would find a 1000-bedded workhouse infirmary in London under the care of some six medical officers. The amount of surgery done was necessarily small; it was of the nature of emergency work, such as colostomy for the relief of intestinal obstruction or of amputation for gangrenous limbs. Now the infirmaries have become municipal hospitals; they have the most up-to-date theatres, first-rate surgical equipment, and a whole-time medical service which is already creating a fine tradition. What a chance this is for surgery to develop; here is a career for young surgeons.

Some people fear that the voluntary hospitals will be overwhelmed and displaced, being unable to compete financially with hospitals maintained by the rates. Personally I am not afraid. If a voluntary hospital falls behind in the race it is its own fault and deserves to suffer. The State is tending more and more to assume the duty of looking after the health of the community. This is to be seen in the public health services and in the formation of clinics for tuberculosis, venereal diseases, child welfare, and others. Now the Local Government Act makes another big step forward by providing institutional treatment. The rich can look after themselves. The poor are also now in a fair way to be looked after. But there is an enormous middle class, who do not come under the Insurance Act and who badly need medical assistance and hospitals to which they can

go when requiring operations. What arrangements can be made for them and how are they to be financed? The answer may be compulsory universal insurance.

FOLLOW-UP SERVICE

Among the governing bodies of hospitals there is a growing consciousness that their duty is not at an end when the patient has had an operation and has left the hospital. There is a further obligation: to the patients in order to ensure uninterrupted convalescence; to the medical officers in order that they may have correct records of the value of the work done. The profession needs records of a national character, not merely the figures of a few gifted and energetic individuals.

The work of the Radium Commission offers an example of what may be done by concerted effort. When this commission founded its national centres an obligation was laid on each to establish a follow-up service and to prepare life statistics of their work. The fruits of this are now appearing as national statistics of the results of radium treatment of certain forms of cancer. It is to be hoped a similar service will rapidly replace the old form of hospital statistics, which amount to little more than a list of various diseases treated.

SURGICAL ASSOCIATIONS

A new departure in post-war surgery has been the formation of surgical associations. In 1920 was founded the Association of Surgeons of Great Britain and Ireland. Surgeons from all over the country meet at stated intervals to exchange views on current surgical topics and, what is perhaps still more important, at these meetings they learn to know each other and to make lasting friendships. Its very success however entails certain moral obligations and it seems to me that a heavy responsibility lies on it and on all British colleges of surgery to help the surgeons of the whole country. It is probably fair to say that the bulk of surgery is done by men who have not taken a special degree in surgery; it would be of great advantage to them and to the country if they could in some way be brought into contact with the progress of work.

Mention should also be made of the development of a number of surgical travelling clubs. These are small groups of surgeons which make a practice of travelling each year to visit some foreign clinic. The advantage of this is manifest for it brings British surgery in touch with all the best work of other countries and many new ideas are brought back to be put into practice at home. Surgery is becoming international, a fact that cannot help being conducive to good feeling among the nations. The Société Nationale de Chirurgie de Paris has asked the Royal College of Surgeons of England to enter into closer relations with it and the response has been cordial.

THE FUTURE

What will be the outcome of these changes going on in the world of surgery? He must be a wise man who can foretell the future; he is a dull one who cannot see what is going on under his own nose. The State or the municipal authorities are assuming more and more the duty of looking after the health of the people. There is a swing against the rather strict limits in which specialism has been confined. Our young men are striving to widen their sphere of action and to gain a mastery of their profession by rendering themselves expert at an early age in the varied and complicated techniques needed for

diagnosis and treatment. There is increasing demand for better organisation of surgery and the development of the team spirit. The disadvantage under which detached workers labour is obvious. We need to make plans on a national scale so that, instead of relying on the chance and rare talents of some super surgeon, we may have succession of effort carried on by generation after generation of surgeons. Let us remember the story of the race of the torch. They were not always the fastest runners who kept their torch alight. The Sphinx—which is Science—was slain at last by a man lame on his feet and was brought home laid on the back of an ass.

JUDICIAL HANGING

THE Medico-Legal Society of Victoria is a young society, founded only in 1931, of which the first volume of *Proceedings* has recently been published.¹ The first paper given before the society, under the presidency of Mr. Justice McArthur, was by Prof. F. Wood Jones, F.R.S., and dealt with the anatomical lesions in judicial executions—a subject, it may be remembered, which he discussed in this journal more than twenty years ago.² Prof. Wood Jones ranges himself with many prison officials and others in holding that a submental knot with a short drop should be adopted by those whose duty it is to carry out the sentence of the law on their fellow-men. There is certainly evidence to prove that complete fracture of the axis follows this procedure, and that it does not certainly follow the use of subaural or suboccipital knots, though Dr. C. Godfrey, in the discussion on the paper, brought forward proof of fracture of the axis in several cases where the knot had been tied under the left ear. The claim for the superiority of the submental procedure would appear to be in keeping with anatomical considerations. Disruption of the base of the skull, which is common when other methods are employed, is not, as Prof. Wood Jones says, an ideal method of procuring death, and the different ways in which this legal necessity may be attained seem to be used in haphazard fashion, and with varying results

Mr. GEORGE BANKOFF writes to disclaim any knowledge or responsibility on his part for the article published on the front page of the *Sunday Referee* of Oct. 20th. Neither information nor photograph was supplied by him or anyone in his employ. The writer of the article was unknown to him.

Dr. ALFRED WILLS, whose death occurred on Oct. 15th at Princes Risborough, where he was partner in a general practice, qualified from Guy's Hospital in 1914. Three years earlier he had taken his B.Sc. Lond. with honours, and in 1921 he went on to take the M.D. degree. He filled house appointments at Guy's and the Croydon General Hospital and served in the R.A.M.C. with the rank of captain. Dr. F. G. Parsons writes: "Wills was one who, had fortune been kinder, would have made an ideal consulting physician, for he was clever, observant, level headed, and kind hearted. I am indebted to him for help and advice in writing the History of St. Thomas's Hospital, with which that of Guy's is so closely blended. If we have succeeded in giving a fair account of the Guy's point of view in describing the frequent and unavoidable differences between the two great hospitals placed for so many years, side by side, in Southwark, it is to Wills's logical brain that most of the credit is due. I am glad to think that his last days were cheered by the knowledge that his son had begun to follow in his footsteps at the famous medical school of which he was so proud."

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
MONDAY, Oct. 28th.

Odontology. 8 P.M. Mr. Cyril Howkins: Mortality and Occupational Diseases of a Dental Surgeon (presidential address). Mr. W. Warwick James: An Improved Procedure for the Removal of Third Mandibular Molars.

FRIDAY, Nov. 1st.

Otology. 10.30 A.M. (Cases at 9.30 A.M.) Mr. Harold Kisch: Review of Petrositis (presidential address). Mr. F. W. Watkyn-Thomas: Treatment of Petrositis. Sir James Dundas-Grant: Measurement of Decibel Hearing Loss by Tuning Forks.

Laryngology. 5 P.M. (Cases at 4 P.M.) Mr. Lionel Colledge: presidential address.

Anæsthetics. 8.30 P.M. Dr. H. A. Richards: presidential address.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.

MONDAY, Oct. 28th.—8.30 P.M., Dr. Macdonald Critchley and Dr. John Aydon: Electrical Injuries.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Oct. 30th.—4 P.M. (St. James Hospital, Ouseley-road, S.W.), Dr. J. B. Mennell: Manipulative Surgery of the Spine.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, Nov. 1st.—8 P.M. (West London Hospital), Dr. C. E. Newman, Dr. H. E. Archer, Dr. H. W. Post, and Mr. Neil Sinclair: Diseases of the Gall-bladder.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

MONDAY, Oct. 28th.—5 P.M., Dr. L. W. Proger: Some Diseases of Bone (I.).

FRIDAY, Nov. 1st.—5 P.M., Dr. A. J. E. Cave: The Anatomy and Physiology of the Human Larynx.

UNIVERSITY OF LONDON.

THURSDAY, Oct. 31st.—5 P.M. (1, Wimpole-street, W.), Sir St. Clair Thomson: Defences of the Air-passages. (Seminar lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 28th, to SATURDAY, Nov. 2nd.—INFANTS HOSPITAL, Vincent-square, S.W. Mon., Wed., and Fri., 8 P.M., F.R.C.S. (Primary), anatomy and physiology course.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. All-day course in gynecology.—VICTORIA PARK HOSPITAL, B. All-day course in chest diseases.—ROYAL ALBERT DOCK HOSPITAL, E. Sat. and Sun., course in clinical surgery.—MEDICAL SOCIETY OF LONDON, Chandos-street, W. Thurs., 4 P.M., Dr. P. N. F. Bishop: Hormone Therapy in Gynecology.—NATIONAL TEMPERANCE League, 1, Old, N.W. Tues., 8.30 P.M., Dr. are open only to members.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, Oct. 28th.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Gynecological and Surgical Wards, Eye and Gynecological Clinics. 4.15 P.M., Mr. Green-Armistage: Regrets.

TUESDAY.—10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Throat Clinic.

WEDNESDAY.—10.30 A.M., Children's Wards and Clinic. Medical Wards. 2 P.M., Eye Clinic, Gynecological Operations. 4.15 P.M., Dr. Archer: Biochemical Demonstration.

THURSDAY.—10 A.M., Neurological and Gynecological Clinics. 12 noon, Fracture Clinic. 2 P.M., Eye and Genito-urinary Clinics.

FRIDAY, Nov. 1st.—10 A.M., Skin Clinic. 12 noon, Lecture on Treatment. 2 P.M., Throat Clinic. 4.15 P.M., Mr. Vlasto: Hoarseness.

SATURDAY, 10 A.M.—Medical Wards, Children's and Surgical Clinics.

The lectures at 4.15 P.M. are open to all medical practitioners without fee. Operations and medical and surgical clinics daily at 2 P.M.

KING'S COLLEGE HOSPITAL, Denmark Hill, S.E.

THURSDAY, Oct. 31st.—9 P.M., Dr. William Brand: The Public Health Aspect of Tuberculosis.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Oct. 28th.—3.30 P.M., Dr. Kinnier Wilson: Organic Dementia (II.).

TUESDAY.—3.30 P.M., Dr. Purdon Martin: Some Disorders of the Ductless Glands.

WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.

THURSDAY.—3.30 P.M., Dr. Riddoch: The Sensory System (IV.).

FRIDAY, Nov. 1st.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (IV.).

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL, N.W.

WEDNESDAY, Oct. 30th.—4 P.M., Mr. D. H. Patey: The Uses of Traction in the Treatment of Fractures and Dislocations.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Oct. 30th.—4.30 P.M., Mr. Claude Mills: Some Interesting Urological Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Oct. 31st.—2 P.M., Dr. R. S. Frew: Pyrexia. 3 P.M., Dr. A. Signy: The Examination of Cerebro-spinal Fluids.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.

TUESDAY, Oct. 29th.—5 P.M., Dr. W. Griffith: Eczema.

THURSDAY.—5 P.M., Dr. A. M. H. Gray: The Sarcoids and Lupus Pernio.

ST. JOHN CLINIC, Ranelagh-road, S.W.

FRIDAY, Nov. 1st.—4.30 P.M., Sir Leonard Hill, F.R.S.: Action of Ultra-violet, Visible, and Infra-red Rays.

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, Oct. 30th.—3.30 P.M., Dr. L. S. T. Russell: Tuberculosis in Youth.

CHADWICK PUBLIC LECTURE.

FRIDAY, Nov. 1st.—5.30 P.M. (26, Portland-place, W.), Dr. G. Killick Millard: The Vaccination Question To-day.

UNIVERSITY OF SHEFFIELD.

FRIDAY, Nov. 1st.—3 P.M. (Royal Hospital), Prof. A. E. Nash: Medical Cases.—3 P.M. (Royal Infirmary), Dr. A. E. Barnes: Medical Cases. 3 P.M. (Jessop Hospital), Prof. Cases.

SUNDAY.—10.30 A.M. Nash: Medical Cases.

Barnes: Medical Cases. Prof. Ernest Finch: Surgical Cases. 10.30 A.M. (Jessop Hospital), Mr. Eric Stacey: Gynecological Cases.

GENERAL INFIRMARY, Leeds.

TUESDAY, Oct. 29th.—3.30 P.M., Mr. Broomhead: Injuries in the Region of the Elbow.

PUBLIC DISPENSARY, Leeds.

WEDNESDAY, Oct. 30th.—4 P.M., Dr. S. J. Hartfall: Nervous Dyspepsia and Gastro-intestinal Neuroses.

ROYAL INFIRMARY, Manchester.

TUESDAY, Oct. 29th.—4.15 P.M., Dr. Fergus R. Ferguson: Recent Advances in Neurology.

FRIDAY, Nov. 1st.—4.15 P.M., Mr. Geoffrey Jefferson: Demonstration of Neuro-surgical Cases.

Appointments

BELL, A. C., M.B. Lond., F.R.C.S. Eng., has been appointed gynecologist to the Eastern Dispensary, Whitechapel.

CORDIMER, R., M.B. Glasg., D.P.H., medical officer for the Borough of Coatbridge.

DUNNE, B. J., M.B. N.Z., medical superintendent at the Drenth Hospital, Greenwith.

GERRIE, JOHN, M.B. Aberd., F.R.C.S. Edin., junior assistant surgeon to the department for the Treatment of Diseases of the Ear, Nose, and Throat, Royal Infirmary, Aberdeen; and hon. assistant surgeon for diseases of the Ear, Nose, and Throat to the Royal Aberdeen Hospital for Sick Children.

GILMOUR, HELEN, M.B. Glasg., pathologist at the Royal Alexandra Infirmary, Paisley.

GORDON-NAPHER, G., M.D. Edin., D.O.M.S., hon. assistant surgeon to the Nottingham and Midland Eye Infirmary.

GREEN, H. N., M.D. Sheff., hon. pathologist to the Jessop Hospital, Sheffield.

KNOWITON, R. W., M.D. Camb., M.C.O.G., antenatal medical officer, gynecologist, and consulting obstetrician for Southampton.

LEVY, S. M.B., ... at the Tilbury Hospital.

PAYNE, G. E., ... ty medical officer of health to

STACEY, J. E., ... hon. surgeon to the Jessop Hospital, Sheffield.

YULE, JOHN, M.D. Glasg., D.P.H., medical officer for Stockport.

Hospital for Sick Children, Great Ormond-street, London, W.C.—The following appointments

WATKINSON, D. J., M.B., R.

GORDON, I., M.B. Aberd., ... and

BRADSHAW, D. B., M.B. Dub., D.P.H., Assistant Medical Officer to the Immunological Department.

Certifying Surgeons under the Factory and Workshop Acts:

Dr. L. R. G. DE GLANVILLE (Rathfriland District, Denbigh).

Dr. W. Bruce (Dingwall District, Ross).

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—The annual prize giving will take place in the board room of the hospital on Wednesday, Nov. 13th, at 3 P.M., when Lord Macmillan will deliver the inaugural address. The annual school dinner will be held at Claridge's Hotel on the same day at 7.30 for 8 P.M.

ADDRESSES AND ORIGINAL ARTICLES

MEDICAL EDUCATION

AN ADDRESS GIVEN AT ADELAIDE UNIVERSITY ON
THE OCCASION OF THE JUBILEE OF THE
MEDICAL FACULTY

By LORD HORDER, K.C.V.O., M.D., F.R.C.P. Lond.,
SENIOR PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

MR. VICE-CHANCELLOR, YOUR EXCELLENCY, LADIES, AND GENTLEMEN,—On behalf of my friend and colleague, Sir Thomas Dunhill, and myself, I desire to thank you, Mr. Vice-Chancellor, and the Council of the University of Adelaide, for the signal honour which you have this day conferred upon us.

That attractive diffidence which is so characteristic of Sir Thomas Dunhill would lead him to demur if for a moment I segregate him from myself and say, quite boldly, that in his case I realise how fitting this honour is. A son of Australia, he has for the past 15 years not only given the homeland the fruits of his genius, but he has shown us all of what stuff his motherland is capable. In the unlikely event of anyone in Australia being in a state of doubt on the point, I would like to say here that my colleague has taken his place in the very first rank of British surgeons and has, as we all know, received the recognition due to him from the highest in the land.

In my own case the position is very different. I am a stranger amongst you. You in Australia have already showered your well-known hospitality upon me, as upon the rest of us who have visited you during the past two weeks, with embarrassing profusion. Such a cordial welcome as you have given us, and such kindness as you have shown, have more than rewarded us for our adventure and for any contributions we have made to the deliberations of the B.M.A. meeting in the Commonwealth. And now you put me still further in your debt by making me an honorary member of your University and inviting me to speak to you. I can only say "thank you" very sincerely and assure you that I shall always value this honour as long as life lasts.

In your generously extravagant references to myself, Mr. Vice-Chancellor, you have mentioned my interest in medical education. "I speak as a fool," but I dare not tell you for how many years I have participated in the making of doctors—first by teaching physiology in what we term the pre-clinical part of the curriculum, then in demonstrating bacteriology, pathology, and morbid anatomy, and for the past 25 years teaching clinical medicine. When I remember that at St. Bartholomew's Hospital Medical College over a hundred men qualify for practice every year, and that nearly 1000 students are scattered over the six years of their training at any moment, the recollection rather appals me. That I have had a hand in teaching about 3000 doctors at some time or other in their course of training brings a feeling of great responsibility and some humility. I may perhaps be forgiven for referring to this matter, since I am anxious that you should know that I do not speak without some experience.

THE CURRICULUM

The logic of the matter would naturally suggest that I refer, in the first place, to the curriculum itself.

And on that I hold strong and definite views. But I do not think this is the place in which to air them. I am more concerned to-day with your own conditions and the things I have seen here. Moreover, this matter of the curriculum is more or less standardised all over the British Empire. This is necessitated by the desirability of accepting diplomas as being of equivalent value in whatever part of the Empire obtained—a great advantage. All the same, you can make your views and your influence felt. That the curriculum is badly in need of revision I have personally no doubt whatever, and it is good to know that this revision is being undertaken. A number of subjects demand attention—genetics or the science of heredity, psychology, and dietetics, to name three important ones that occur to me. But the curriculum is already over full, say some. Agreed, then we ought to take out parts of those subjects that are, relatively to these and others I might mention, unimportant. If the pre-clinical studies in particular are more closely adapted to the special requirements of the budding doctor, invaluable time may be saved. That the clinician should spend many hours teaching the student in the wards and in the out-patient room, facts which really belong to physiology and anatomy and chemistry, is heartbreaking. And it is equally heartbreaking to find, towards the end of his curriculum, that there is no time to teach him the subjects to which I have referred. I regard this matter as so vital that I think nothing has given me greater satisfaction, Mr. Vice-Chancellor, than to hear from you that in Adelaide University the scientific subjects are taught to those students who are intending to become doctors, with due recognition of this fact, so that a maximum concentration is made upon the ultimate purpose of their career from the very first.

You are fortunate in Adelaide, as elsewhere in the Commonwealth, in that the only avenue of entry into the medical profession is through the University. You are aware, Mr. Vice-Chancellor, of the difficulties and complications in this matter at home, where a large percentage of our doctors take an extra-university diploma. Now this latter procedure has at least one saving benefit: it keeps the student in very close touch with his hospital. And that is essential. The teaching of medicine differs fundamentally from the teaching of any other profession in this—that its success is entirely dependent upon close contact between the student and clinical material, that is, the patient. It was a dictum of the great French clinician, Trousseau, "les malades, toujours les malades," a dictum which might well be written up in large letters over the entrance to a medical school. That is another reason why the pre-clinical studies should not be too long drawn out. They are necessary, vitally necessary; but the sooner the embryo doctor comes in contact with the patient, and keeps this contact, the better for both of them. Of course the young doctor should have made contact with his fellows long before this, and should have trained himself to observe. The power of observation and an intense interest in human beings are much better indications that a boy will make a good doctor than finding him dissecting a fly or ill-treating a frog, which are the more traditional signs that he was destined for the career of medicine. As I say, this close fusion of the academic with the clinical aspects of his work is paramount for the medical student. Your facilities for this in Adelaide seem

to me to be quite exceptional. Quite apart from your aesthetic advantages, and the amenities of quiet, air, and light, the geographical features are ideal. The proximity of the university to the hospital is such that the liaison can be of the closest. A stone's throw separates the class-room and the lecture theatre from the wards, the out-patient rooms, and the special departments. In passing, I should like to congratulate the hospital authorities upon the magnificent lay-out of the buildings and their perfect adaptability to hospital needs. The wards combine the best hygienic conditions with that touch of homeliness which is so important a factor in the patient's recovery.

THE PLACE OF RESEARCH

If I miss anything in all this paradise of hospital service and university culture—and it is a product of that experience of which I spoke when I began that it gives one the power of detecting the weakness as well as the strength of any system of medical education—if I miss anything, it is in the field of research. But as soon as I inquire about this I am made aware of efforts already under way towards repairing this breach in what is otherwise such an attractive and efficient edifice. I understand there is a scheme afoot by which all this valuable clinical and pathological material shall be utilised, not only for the direct teaching of medicine, but for the furthering of medical science and medical treatment.

Quite apart from the enormous value of such a scheme in this direction, its value in raising the prestige of the university and of the hospital still higher, and its moral effect upon the student at every step in his career, will be incalculable. Such an "Institute of Medical Science" would knit together the present hospital service, the clinico-pathological investigations, and the post-mortem findings as nothing else could do. I spoke of the moral effect upon the student. May I, with all deference, speak of the moral effect of such an institute upon the teachers? That, too, would be incalculable. I do not know what departments are so far envisaged in the new block which, I assume, such a conception would make necessary. But I imagine they would include one in which the clinico-pathological investigations are analysed and correlated; another in which the invaluable post-mortem materials are studied in greater detail than can be done in the post-mortem room itself; still another which is devoted to public health affairs; and a series of small laboratories for researches undertaken by the staff, and by senior students. The present museum would probably be transferred to one floor of the building. I have no doubt that all sections at present controlling and administering the hospital and the medical school will work enthusiastically towards this project, so essential to the professors, the students, the doctors, and the public. How truly have you said, Sir, "the function of a medical school is not only to spread knowledge, but to make it."

ESSENTIALS IN EQUIPMENT

I am speaking to-day on a memorable occasion in the history of the Medical School of the University of Adelaide. This year the school celebrates its jubilee. Fifty years may seem a short time, but we must not forget that medical teaching, of any systematised sort, has only existed anywhere in the world for about twice that period. And whatever

we may think about the Art of medicine, the past 50 years comprise practically the whole of the Science of present-day medicine. You think you are young, but much of what was taught to the medical student 50 years ago is already outworn, if not positively dangerous. If anyone in Adelaide, concerning himself with the teaching or with the learning of medicine, thinks he lacks advantages which we at home enjoy, let him get rid of that particular thought as soon as possible. For what are the essentials in the equipment of the good doctor? There are the traditions of our profession to begin with. The imperishable nature of these, and their enormous influence upon the medical man—and therefore their great value to his patients—cannot be exaggerated. But these traditions are shared equally by young medical schools and old. They date back at least 2000 years. Next comes the calibre of the young doctor himself. I have had many Australians amongst my students, and I am quite sure that in brains, and in personality, they take a place second to none. Do I see the best of them perhaps? If I do, then so much the better for me. I think it is a pity that more of them do not come back to the land of their birth and of their early training—a land to be proud of and to work for. Not that we do not like them to remain with us: personally, to use a vulgarism, I "fall for them" every time, as I do for Irishmen and for sailors. But ought we to keep these men and these women? My conscience is a little disturbed about them, because I am not clear that we deserve the best that you produce. Moreover, if a country creams off even a portion of its best men and women, and loses them, and loses their offspring, though this may be a great gain to others, it must inevitably be a loss to the land that bred them.

Next comes the personnel of the teachers. I can concede nothing on this point. Great names have emerged from Adelaide. You, Sir, have already mentioned some of these: Bragg, Rennie, Stirling, Robertson, Watson, and Virco, concerning whom you, Sir, have spoken so eloquently (and who I had formerly thought had no vice until you told us that he never took a holiday. It is good and encouraging to know that Joseph Virco was no better than the rest of us)—to say nothing of those stalwarts who are still with you, and concerning whom it were invidious to speak. Then again, Adelaide has made large contributions to the teaching staffs of other schools in the Commonwealth. Lastly, the materials for teaching. I have already dealt with these. There is more than a quarter of a million people to feed the hospital and 500 beds to cope with this population, so that the fear at present is a wastage of clinical material rather than a paucity of it. It is my bent to look for what, to use another vulgarism, are termed "snags." I can see none. Unless it be this Institute of Medical Science within your walls, the contemplation of which has now led to the beginning of practical measures, and whose establishment would be a fine tribute to the work which the school has done in the past 50 years.

On behalf of my colleague and myself I offer the Medical School of Adelaide our warm congratulations upon the attainment of its jubilee. With traditions that it shares with all of us, with ideals which are no less high than those that imbue Australians in general, with unexcelled advantages, both academic and practical, it can surely not fail to achieve that success in the future which we so ardently desire for it.

ACUTE PANCREATITIS IN CHILDHOOD

REPORT OF A CASE

BY R. H. DOBBS, B.Chir. Camb.

LATE RESIDENT MEDICAL OFFICER, THE PRINCESS ELIZABETH OF YORK HOSPITAL FOR CHILDREN, LONDON

ACUTE pancreatitis of severe degree is rare in childhood. Mild attacks of what is presumed to be pancreatitis occasionally develop as a complication of some of the acute specific fevers, notably mumps. Farnham¹ collected 119 cases of mumps pancreatitis all but 2 of which recovered without operation. Of these 2, one was operated upon and later made a complete recovery, and the other, originally reported by Lemoine and Le Passet,² came to autopsy. In both of them typical acute pancreatitis was found.

Apart from mumps the condition is extremely rare in children, and it may be useful to give an account of a case recently under the care of Dr. Leonard Findlay, at the Princess Elizabeth of York Hospital, with a summary of 14 others I have found on record in which the patient was under fourteen.

CASE RECORD

The patient, a girl 12½ years old, was admitted on June 11th, 1934, suffering from headache and vomiting. The birth and development had been normal, and the clinical history had been uneventful until this year. She had contracted measles, diphtheria, and (be it noted) mumps by the age of 6, and had had two attacks of erythema-nodosum [sic], one at 9 years and one in April, 1934. Her subsequent history both before admission and during the first few weeks in hospital, though of great interest in a different connexion, scarcely needs detailed reporting.

The story was that late in April, soon after the second attack of so-called erythema nodosum, the patient had fallen ill with left-sided earache and aural discharge, which some ten days later was followed by mastoid tenderness. She was transferred to the local hospital where the discharge and tenderness subsided. On May 21st, however, she had fever, headache, and nuchal rigidity, and a lumbar puncture was performed. The fluid was sterile but contained 400 cells per c.mm., of which 70 per cent. were polymorphonuclear. The condition once again subsided, but early in June headache, vomiting, and nuchal rigidity returned; the patient became drowsy, in which state she remained until her admittance to this hospital on June 11th, 1934.

On admission to the Princess Elizabeth of York Hospital the patient had a subnormal temperature, a slow pulse-rate, a slight right-sided facial paresis, and a nominal aphasia, which made it clear that she had a left-sided temporo-sphenoidal abscess. On June 15th the abscess was needed through a half-inch trephine hole by Mr. Charles Keogh, and 30 c.cm. of thick yellow pus was withdrawn from which *Streptococcus pyogenes* was grown. The patient after a few stormy days appeared to make an uneventful recovery. It may be noted that at no time whilst in this hospital did she have any aural symptoms, and that the ear appeared normal on inspection, as did the mastoid region on physical and radiological examination, and that no operation was undertaken beyond the trephine hole three inches above and two inches behind the root of the zygoma.

The patient appeared to be doing excellently when, on June 27th, the twelfth day after drainage of her cerebral abscess, she was taken suddenly ill at 3 A.M. with severe abdominal pain and repeated vomiting. When first examined during the morning round, the patient pointed to the epigastrium as the site of her pain, but the abdomen was lax and no physical signs could be elicited beyond tenderness on deep palpation in the epigastrium and those of a general nature—i.e., she was shocked, had a temperature of 97° F., and a pulse-rate between 90 and

100. It then transpired, only from the assertion of the child aged 9 years in the next bed, that the day before the patient had attempted to get out of bed when no nurse was looking and had fallen face downwards across the side of the bed. She had thereupon got into bed laughing but admitted that she had hurt her "tummy" slightly. The significance of these symptoms not at first being realised, it was thought that the return of vomiting indicated a relapse of the cerebral condition. The abdominal pain remained on this basis unexplained.

The abdominal pain and repeated vomiting continued throughout that day and the next, and on June 29th, two days after the onset, the condition of the patient was much the same but the rectal temperature had risen to between 99° and 101° F., the pulse-rate to 120–130, and a slight but definite rigidity mainly of the right rectus made its appearance for the first time. A blood count showed a leucocytosis of 42,000, of which 92 per cent. were polymorphonuclear, and the urine contained no albumin, pus, or sugar. A diastatic index was not performed. A provisional diagnosis of acute appendicitis was made, though it was realised that this was unsatisfactory.

An exploratory laparotomy was determined upon and carried out by Mr. H. W. S. Wright. The abdomen was opened through a right paramedian incision. On opening the peritoneum a large quantity of slightly blood-stained fluid escaped; the great omentum was engorged and oedematous and thickly studded with areas of fat necrosis; the duodenum and under-surface of the liver appeared normal; the pancreas was very hard and moderately enlarged; the gastrocolic omentum over the pancreas was engorged and also studded with fat necrosis; the gall-bladder and bile-ducts were palpated and appeared to be normal but were not explored. The condition was diagnosed as acute pancreatitis, and a drainage-tube packed round with gauze was put down to the surface of but not into the pancreas; a second tube was inserted beneath the liver and the abdomen was closed.

A specimen of urine collected immediately after operation showed a diastatic index of 512 units, compared with 16 units of a control patient's urine.

The patient made a rapid recovery. There was some vomiting for the first 24 hours and the skin round the wound became sore and slightly septic for a week. The packing was removed on the 12th day and the tube on the 14th day. By the 26th day the wound was healed and the child again well. She was sent to a convalescent home, and on Sept. 11th, just three months after admission, she was well and lively with normal ear-drums, a healed trephine wound, and healed abdominal wound; and by Nov. 6th the diastatic index had returned to normal.

The results of the urinary diastatic estimations show the gradual return to normal during the course of 18 weeks:—

Date in 1934.	Patient.	Control.
June 29	512 units.	16 units.
July 2	128 "	16 "
" 9	64 "	16 "
" 23	64 "	16 "
Sept. 11	32 "	16 "
Nov. 6	16 "	16 "

This history has several features of interest. It may be noticed in passing that there is an alleged second attack of erythema nodosum. This, though it has been reported, is not common, and reliable cases are rare. It is significant that the Mantoux reaction to 1/1000 tuberculin was negative on admission.

The patient contracted acute pancreatitis whilst under observation in hospital, two weeks after a large collection of pus had been removed from a quite remote part of the body. At the time it seemed possible, even probable, that there was a relationship between these two events, and the literature of the subject was examined to ascertain, first, the frequency of acute pancreatitis in children, and,

secondly, whether remote sepsis is commonly an ætiological factor.

FOURTEEN RECORDED CASES.

The cases discovered may be summarised as follows:—

CASE 1 (Herzog³).—Child of 2 years, previously healthy. Sudden onset of pain followed by repeated vomiting. The pain subsided in a few hours, but vomiting was repeated and patient's condition gradually worsened and he died suddenly 22 hours after onset of first symptoms. Post mortem a six-centimetre round-worm was found mixed with vomit in the hair near right ear. Peritoneal cavity blood-stained but no free fluid; many areas of fat necrosis in mesentery and colon; pancreas dark red with many hæmorrhagic areas throughout its substance. Cause: ? due to round-worm.

CASE 2 (Gallie and Brown⁴).—Boy, aged 2½. Sudden abdominal pain, doubling up, pallor, and repeated vomiting for nine hours when pain ceased. Obstreperous child, did not appear ill. Under anaesthesia, firm fixed abdominal tumour felt in epigastrium. Operation 48 hours after onset: blood-stained fluid in peritoneal cavity; tumour found to be very firm swollen pancreas; pancreas and omentum covered with areas of fat necrosis; gall-bladder distended but emptiable; biliary tract normal; abdomen closed without drainage. Uninterrupted recovery. Vomited round-worm 15 hours after operation. Cause: ? due to round-worm.

CASE 3 (Holzman⁵).—Boy, aged 3. Sudden abdominal pain; passed blood per rectum; vomited. Seen 24 hours later he was much shocked; abdomen full, tender, resistant in epigastrium. Operation: blood-stained fluid in peritoneal cavity; nil else abnormal, except very red in pancreatic region. Patient died. Post mortem: fat necrosis all over peritoneum, mesentery, and pancreatic region; pancreas swollen and red, cross-section showed many hæmorrhagic areas; biliary tract normal. Cause: none found.

CASE 4 (Mackenzie⁶).—Girl, aged 3 (congenital idiot). No history of mumps. Patient suddenly collapsed and died. She had had follicular tonsillitis two weeks previously, since when she had been of a poor colour and had had occasional attacks of vomiting with abdominal discomfort. Post mortem: fat necrosis on mesentery and complete necrosis of pancreas. Cause: ? septic embolus in pancreas.

CASE 5 (Anderson⁷).—Girl, aged 4. Sudden onset of abdominal pain; vomited repeatedly; much shocked. On examination three hours later: abdomen distended, not rigid; vomiting repeatedly. Patient died an hour after admission to hospital. Post mortem: 200 c.cm. blood-stained fluid was found in peritoneal cavity; areas of fat necrosis on omentum and large intestine; retroperitoneal hæmorrhage over transverse colon; biliary tract normal; acute duodenitis; pancreas swollen and œdematous, section showed many hæmorrhagic areas. Cause: unknown.

CASE 6 (Désjardins⁸).—Boy, aged 5. Two hours after midday meal complained of sudden violent abdominal pain; vomited. Two days later admitted to hospital; vomiting continuously, much shocked, with distended abdomen and blue discoloration around the umbilicus. Operation: blood-stained fluid in abdominal cavity; fat necrosis on mesentery; abdomen closed. Second operation on eighth day for evacuation of more fluid. Patient died seventeen days after onset. Post mortem: head of pancreas entirely necrotic; biliary tract normal; no helminthiasis. Cause: unknown.

CASE 7 (Hagedorn⁹).—Boy, aged 7. Run over by cart; wheel crossed abdomen. Immediate severe abdominal pain and repeated vomiting. Operation twenty-four hours later: blood-stained fluid in peritoneal cavity; fat necrosis on mesentery and omentum; no visible or palpable lesion of pancreas. Abdomen closed without drainage. Healed in eight days. Urine never contained sugar. Cause: trauma.

CASE 8 (Phélip¹⁰).—Child, aged 7. Typhoid at 6. Sudden onset of violent abdominal pain; immediate and repeated vomiting. Four days later: pale, ill child with "peritoneal aspect"; abdominal tenderness, no rigidity; transversely placed tumour high up in the epigastrium. Operation: tumour in mesocolon covered with yellowish areas of fat necrosis. Patient died five days after onset. Post mortem: no free fluid; tumour revealed as firm swollen pancreas; biliary tract normal. Cause: unknown.

CASE 9 (Dietrich¹¹).—Boy, aged 10. Fell in front of cart; wheel crossed upper abdomen; complained of great pain and vomiting, which persisted for ten days. Examination ten days after accident: very ill child in great pain; abdomen distended and everywhere tender. Operation: no free fluid in cavity; round cystic swelling, size of hen's egg, containing whitish sterile fluid, above transverse colon; pancreas covered with fat necrosis. Patient very ill for three days; sugar found in urine. Eventually recovered. Cause: trauma.

CASE 10 (Foged¹²).—Girl, aged 11; previously healthy. Vague abdominal pain for last three months; sudden onset of paroxysmal abdominal pain and frequent vomiting; patient's condition became considerably worse during course of three days. No urinary symptoms or jaundice; urine clear. Abdomen distended; tenderness everywhere; soft mass felt in right iliac fossa. Operation third day after onset: blood-stained fluid in peritoneal cavity; fat necrosis on mesocolon and omentum. Patient died soon after operation. Post mortem: large retroperitoneal mass of blood; many fat necroses everywhere; pancreas enormous, infiltrated with blood; biliary tract normal; no helminthiasis. Cause: unknown.

CASE 11 (Novis¹³).—Hindu girl, aged 12. Onset of severe abdominal pain with vomiting. Condition subsided but pain returned without vomiting during the next eight days. Examination: thin girl, did not appear ill; abdomen not distended; rigid right rectus and tender swelling in epigastrium; urine normal. Observed for a week and had attacks resembling biliary colic. Operation about two weeks after onset: no free fluid; pancreas greatly enlarged; pancreas incised and two round-worms picked out from length of pancreatic duct; pancreas stitched and abdomen closed. Patient passed several round-worms after administration of santonin. Recovery uninterrupted. Cause: round-worms.

CASE 12 (Dobrowsky¹⁴).—Girl, aged 12. Ran heavily into a barrier; forty-eight hours later severe abdominal pain. Operation: blood-stained fluid and fat necrosis in peritoneal cavity; large hæmatoma of pancreas. Abdomen closed. Patient recovered. Cause: trauma.

CASE 13 (Vogel¹⁵).—Girl, aged 13. Operation undertaken for severe acute pancreatitis. Patient died. Post mortem: typical acute pancreatitis; common opening of pancreatic and common bile-ducts. Cause: unknown; ? congenital abnormality.

CASE 14 (Sobening¹⁶).—Girl, aged 13. Operated on for cholelithiasis. At operation a stone was found impacted in papilla of Vater; fat necrosis on pancreas. Stone removed. Patient recovered. Cause: cholelithiasis.

COMMENTARY

The signs and symptoms, though not pathognomonic, are at least suggestive, and occurring in an adult would, I feel confident, give rise to a suspicion that the pancreas might be at fault. In every case except two, in which no mention was made, there was a history of a sudden onset of severe abdominal pain and repeated vomiting, both lasting until operative measures or death supervened. Examination revealed shock, usually of considerable extent, with generalised abdominal tenderness and, as a rule, a significant absence of marked abdominal rigidity. In the adult attention is often drawn to two further signs which might suggest the diagnosis.

First, a cyanotic or livid hue of the face, supposed to be brought on by interference with the movement of the diaphragm; secondly, a blue discoloration of the external abdominal wall around the umbilicus, which is of course produced by an infiltration of altered blood pigments through the parietes from the blood-stained fluid within the peritoneal cavity. In no case was the former, and in only one—No. 6—was the latter sign mentioned; and in this case the question was not pursued further.

Finally, when acute pancreatitis is under consideration, three laboratory tests may be made: Loewe's eye test, Cammidge's test, and Wöhlgemuth's urinary diastase estimation; the last of which at least will establish the diagnosis beyond question. Cohnheim¹⁷ knew of and described a starch-splitting ferment in the urine of normal subjects as long ago as 1863. In 1908 Wöhlgemuth¹⁸ worked out a method of estimating this substance, and later he,¹⁹ and in this country Corbett,²⁰ established the value of the urinary diastatic index in the diagnosis of acute pancreatitis.

Ætiology.—In 6 cases no definite cause was found. In one (No. 13) a congenital abnormality of the ducts was present, and in another (No. 5) acute duodenitis; but it seems idle with such scanty evidence to speculate upon possible ætiological factors.

Trauma accounted for 4 cases. This is a rare but well-recognised cause of acute pancreatitis. Dietrich,¹¹ in a long article on pancreatitis, has a section on "Pancreatitis acuta traumatica," and Leith²¹ quotes 7 cases due to crushing accidents, severe blows in the epigastrium, or abdominal shot-wounds. Experimentally, the disease appears to be very difficult to produce in this way. Brocq, who discards trauma as an ætiological factor, produced bruising and even complete pulp of the pancreas with a hammer, but invariably the animal (dog) had to be killed some days later to reveal only hæmatomata of the pancreas, or, as he laconically puts it, "Tête du pancreas couleur lie de vin," with no evidence of liberation of pancreatic ferments.

Round-worms were certainly the cause in one case (No. 12), and presumably in two others (Nos. 1 and 2). Rigby²² reports a similar case with a fatal issue in which, post mortem, a round-worm was found protruding from the papilla of Vater and lying in the duct of Santorini; and Sabrazès, Parcelier, and Bonnin²³ collected 19 cases in which *Ascaris lumbricoides* was found in the pancreatic duct. Of these, four (Rigby's, Novis's Case 11, and two others) had clinical pancreatitis, and one other had a pancreatic cyst. It is not difficult to see how the presence of a foreign body in the pancreatic duct could allow bile or duodenal contents to enter and activate trypsinogen with consequent pancreatitis.

In one case (No. 14) the disease was of the adult type, occurring together with acute cholelithiasis.

Lastly, in one case only (No. 4) was there any mention of sepsis elsewhere in the body, the patient dying suddenly a fortnight after an attack of acute follicular tonsillitis. Complete necrosis of the pancreas was found post mortem, which must have developed gradually and possibly followed an embolic abscess from the primarily infected tonsils.

It will be seen that there is little evidence either to oppose or support the contention that, in the present case, the brain abscess was primary to an embolic pancreatic abscess. The only other group the case might be placed in, besides the largest one of "cause unknown," is that of trauma. The history of injury was, however, only on the testi-

mony of another child and was probably only slight; there were no symptoms until twelve hours later, though Dobrowsky's case (No. 12) shows that the onset is not always immediate.

Treatment and Prognosis.—Including the present case, 12 patients were operated upon, of whom 7 recovered. Three others died before operation could be undertaken. It is thus difficult to assess the value of operation, but it seems probable that an outlet for the pancreatic ferments and the blood-stained fluid which always collects will at least cut short the progress of the disease, and from this point of view the sooner operation is undertaken the better. The ultimate prognosis, if the operation is survived, is uniformly good. There appeared to be complete recovery in every case and no symptoms referable to the pancreas are mentioned after the patients had been discharged from hospital. Our own patient was quite fit in nine weeks, though it is interesting to note that the urinary diastase did not return to normal until a few weeks later.

SUMMARY

(1) A case of acute pancreatitis in a child aged 12, following upon a brain abscess, is described. The ætiology is discussed in the light of 14 other cases here summarised. (2) Acute pancreatitis in childhood is usually an accidental finding at an abdominal operation or post mortem. This is due partly to the rarity of the condition, and partly to the fact that its causes are quite different from the commonest causes of acute pancreatitis in the adult. The symptoms and signs may be sufficiently distinctive, however, to arouse suspicion of the true nature of the condition and the suspicion can be confirmed by the urinary diastase test. (3) Acute pancreatitis in childhood is very seldom ætiologically related to a diseased biliary tract. Trauma accounts for many cases and *Ascaris lumbricoides* for a few; but in the majority no cause is found. Septic emboli lodging in the pancreas may occasionally be responsible. (4) Operation should be undertaken promptly to allow of rapid removal of destructive ferments and the blood-stained fluid which is always present.

My thanks are due to Dr. Leonard Findlay for permission to report this case and for many helpful suggestions.

age of 3 years has practically 100 per cent. mortality. Close, after discussing 17 cases in which resection was performed without a single recovery, mentions the following case: "It may be a significant fact that in one patient who survived in spite of a gangrenous intussusception, no resection was undertaken and that a spinal anæsthetic was given. A lateral anastomosis was made above and below the obstruction which was left in situ."³

A modified type of resection operation, which has the advantage that no anastomosis has to be made, is that suggested by Bowerman Jessett and first performed by A. E. Barker. In this operation the neck of the intussusception is stitched and the gangrenous intussusceptum is removed through an incision in the ensheathing layer. Some successes have been claimed, but technical difficulty and risk of sepsis at the time of operation, and the liability to stenosis at the neck later, make it an unreliable procedure.

Resection is the usual treatment adopted because attention has been focused on the gangrenous intussusception as a possible source of peritoneal infection or severe intestinal hæmorrhage. But it has been shown that even in fatal cases untreated by operation peritonitis is rare, as the gangrene is limited to the intussusceptum and the ensheathing layer is usually healthy. The alternative, an artificial anus, always seems to be unsatisfactory in children, especially in this condition, since the drainage from the small intestine produces rapid and usually fatal dehydration.

Lateral anastomosis relieves the obstruction and largely avoids the shock and dehydration associated with resection and ileostomy respectively. This method of treatment was first advocated by Parry⁴ in 1909 when reporting a successful case in a child aged 6 months. Rutherford⁵ in the same year published a second success with the same method, and more recently Montgomery and Mussil⁶ have described two more cases of infants 7 and 8 months old.

CONCLUSIONS

(1) Intussusceptions which on laparotomy prove to be irreducible have often shown indefinite signs and symptoms before operation. (2) The lethal factor in these cases is intestinal obstruction, while peritonitis originating from the gangrenous loop is a rare complication. (3) When the element of obstruction is removed, no serious ill-effects have been observed from the retention of gangrenous intestine in the bowel for several weeks. (4) Lateral anastomosis to short-circuit the obstruction offers the best chance of recovery.

STAFFORDSHIRE MENTAL HOSPITALS.—At a meeting of the Staffordshire Mental Hospitals board it was reported that the Cheddleton Mental Hospital visiting committee have accepted tenders amounting to approximately £60,000 for the provision of an admission hospital, convalescent villas, and additional accommodation for nurses. At Stafford and Burntwood, the other two hospitals administered by the board, there is also considerable overcrowding.

PYROTHERAPY IN DEMENTIA PRÆCOX

By DUNCAN MENZIES, M.B. St. And., D.P.M.

DEPUTY MEDICAL SUPERINTENDENT, PLYMOUTH MENTAL HOSPITAL

TREATMENT by the injection of fever-producing substances, termed pyrotherapy or protein shock, has been tried in many conditions. The moderate success attained in neurosyphilis has led to trial of this method in other diseases of which the organic basis is still uncertain.

Dementia præcox is responsible for about 16 per cent. of all admissions and 60 per cent. of chronic cases in public mental hospitals. The hopelessness of the prognosis makes empirical treatment the only alternative to the fatalistic attitude which is so universal. At Plymouth Mental Hospital the means of inducing fever which we have used are Sulfosin and a preparation called Dmelcos. In all, 34 female patients have been treated up to the end of 1934, 7 by sulfosin and 27 by dmelcos.

Sulfosin, a suspension of sulphur in oil, has been used since 1927 by Schroeder.¹ In 1927 Minski² reported a series of 20 cases with 2 recoveries, 1 much improved, 1 short remission, 1 much worse, 15 showing no change. As recommended by Schroeder, sulfosin was given intramuscularly on the lateral side of the thigh between the upper and middle thirds of the femur. Beginning with a small dose (1 c.cm.) injections were given twice weekly over a course of twelve injections; the dose was gradually increased up to 10 c.cm. according to the response. Temperatures up to 104° F. were obtained. Sometimes a secondary rise occurred on the second day after the injection. No abscesses or other complications were produced. Some pain and stiffness at the site of injection were relieved by hot fomentations. This painful reaction is the chief objection to the treatment.

Mackay³ believes that the fever is caused by the liberation of protein from necrosed muscle and so sulphur-therapy can be regarded as a form of protein shock.

Dmelcos, a stabilised atoxic vaccine of Ducrey's bacillus, is given intravenously. No local reaction has been observed even when it has been accidentally injected into the subcutaneous tissues. The vaccine is primarily intended for the treatment of soft sore and its complications. The course consists of six injections of 1, 1.5, 2, 2.5, 3, and 3 c.cm. respectively, each cubic centimetre containing 225 million organisms. Injections are given on alternate days. The rise in temperature was rapid commencing 4-14 hours after the injection; the maximum was reached in about 4 hours; the fall to normal in 5 or 6 hours; the whole reaction lasting for 9 or 10 hours. Rigors were observed in about half the cases. The initial dose of 1 c.cm. produced a temperature of from 101° to 102° F.; afterwards rises up to 104° F. or higher were common. In 4 cases of this series a second course of six injections was given with similar results. In 12 cases the injections were given on consecutive days with no untoward results.

In addition to the usual signs of fever—such as flushed face, headache, rapid pulse, and thirst—vomiting occurred in many cases. But on each occasion the pulse-rate fell with the temperature. Diet consisted mainly of fluids during the fever and aperients were given when required. Towards the end of the course the tongue was furred and the patients showed signs of exhaustion. Loss of weight was negligible and all the physical signs cleared up immediately on cessation of the injections.

In 24 cases there was an immediate response; the remaining 10 showed no appreciable change. The improvement was most marked in the katatonic type. While it lasted, violent and impulsive patients became manageable and easily nursed in an open

dormitory; mute resistive patients became talkative; even stuporous cases appeared more aware of their surroundings. Unfortunately these promising reactions persisted for only a few days in 9 cases. In 5 of the series the patient had a period of from two to three weeks in which she was more accessible, and 6 were sent to the occupational therapy department where the remission persisted for periods up to three months. These had previously been found unemployable by reason of negativism or simple apathy. Four patients were discharged as recovered.

TREATED AND UNTREATED CASES COMPARED

From 1932 to 1934, in order to assess the value of the treatment, all cases of dementia præcox admitted to the hospital were given pyrotherapy. Controls were provided by searching the hospital records for dementia præcox admissions in the period 1928-30. Most of these are still resident with all the symptoms well established; so that the original diagnoses can hardly be called in question. Care was taken to exclude all doubtful cases among the recent admissions. Thus a fair basis of comparison between the treated and the untreated was established.

The results of this investigation were as follows:—

			1932-34 Treated.		1928-30 Untreated.
Recoveries	..	..	1		1
Partial remissions	..	..	2		—
Transferred	..	..	4		—
Died	..	..	1		2
Chronic	..	..	11		14
Total	..	..	19		17

At first glance these figures may not appear to offer much recommendation for the treatment. The recovery-rate remains the same in spite of the labour involved in giving injections, the extra work thrown upon the nursing staff, and the expense borne by the hospital. No form of special therapy, however, can be considered apart from general treatment which, in dementia præcox, is mainly directed towards bringing back the patient to reality, and remoulding the personality. The chief value of pyrotherapy is that it temporarily breaks the vicious circle, and makes the schizophrenic patient more approachable and amenable to suggestion. About one-third of the cases classified as chronic are now usefully employed in handicrafts. Many have had further courses of pyrexial treatment with marked benefit. In course of time, as occupational therapy becomes more highly organised, it is hoped that many more will be saved from complete deterioration. Pyrotherapy, then, can be regarded simply as an introduction to the only rational form of treatment, which is psychotherapy disguised as intensive occupation. The simplicity of technique and absence of dangerous complications makes treatment by sulfoxin and dmelcos eminently suitable for public mental hospitals.

CASE-HISTORIES

The following summaries show the course of the illness in those patients who recovered.

CASE 1.—Female, aged 27, married. Father insane and committed suicide. Previous history: born in Hong-Kong of English parents; contracted malaria in childhood; reserved by nature, but could be jolly on occasion; a good tennis player. Present illness began in May, 1931; she attempted suicide by gas poisoning and was admitted to hospital in June, 1931. On admission was extremely negativistic, refused food and resisted treatment and smeared herself with faeces; had bouts of senseless rage and meaningless laughter; stripped herself naked;

said her head and body were not her own and that she was a boy not a woman; made violent attacks on staff and other patients; required seclusion; physical condition excellent. She continued in this state until April, 1932, when dmelcos was given. The highest temperatures recorded after each injection were 102.3°, 103.6°, 102.6°, 102.6°, 102.2°, and 102.6° F. She had no rigors but vomited twice. There was an immediate response to the fever; she became more talkative and conversed rationally with her husband. She was no longer faulty and destructive and could be nursed in an open dormitory; she relapsed slightly in May, 1932, when sent home on four days' leave. She continued with light handiwork occupation until discharged in March, 1933. Examined a year later, she appeared to have made a complete recovery which has been maintained up to the present.

CASE 2.—Female, aged 19, single. Mother had a nervous breakdown following childbirth. Previous history: normal childhood; became a domestic servant; was said to be devoted to her father; was a rather serious, religiously inclined young woman; had quinsy four months before her mental illness with good recovery. Present illness: onset sudden after a period of insomnia; became restless, noisy, confused, and talked incessantly; admitted to hospital as a temporary patient in November, 1931. On admission was noisy, restless, divorced from reality, manneristic, faulty, and degraded in habits; she refused food and had to be artificially fed; physical condition moderately good. She continued in this state hallucinated, destructive, resistive, and inaccessible; lost weight rapidly. In April, 1932, dmelcos was given; highest temperatures recorded were 102.6°, 103.6°, 103.4°, 102.4°, 102.4°, and 102.4° F. There was no immediate improvement except that she became more docile and easily nursed. In the next three months she rapidly put on weight. She gradually made a partial readjustment under continued directed occupational therapy. Discharged in August, 1932, rather fatuous but with some insight. Recovery completed at home where she has remained well up to the present.

CASE 3.—Female, aged 21. Family history, negative. Previous history: rather a spoilt child brought up in religious atmosphere; admitted masturbation; was a mental nurse for a short period but showed no application. Present illness began one month before admission; she became moody, obstinate, and said she had lost her soul; tried to jump out of window and destroyed clothing. She was admitted to mental hospital under certificate in June, 1934. On admission she was in good physical condition, but dull, apathetic, and indifferent to her surroundings; later she became over-active, destructive, and impulsive; expressed ideas of death, masturbated openly; showed negativism, giggled foolishly, and grimaced. A course of dmelcos was given in July, 1934. Highest temperatures recorded 100.2°, 100°, 100°, 100.4°, 100°, and 100° F. After the injections she was more easily managed and her habits improved. She remained, however, dreamy, self-centred, and inclined to withdraw from others. Sent to occupational therapy department and proved a rapid and efficient worker. Had slight relapse in August, 1934, but gradually improved and was discharged in September, 1934, as recovered. Improvement maintained.

CASE 4.—Female, aged 27, married. Grandmother alcoholic. Previous history: intelligent, highly strung and given to worrying over trifles; she had a child four months before admission. Present illness: after a brief period of depression in which she expressed ideas of unworthiness, she passed into a mute resistive stuporous state; admitted to hospital in November, 1931, as a temporary patient; physical condition good, passed into excited phase; impulsively violent, erotic, faulty in habits; degraded and destructive. Dmelcos was given in April, 1932. Highest temperatures recorded 102°, 104.4°, 103.6°, 103°, 103.2°, and 102.4° F. Improvement followed immediately and she was passed on to occupational therapy department. She continued to be dreamy and self-absorbed, with feelings of unreality and a tendency to negativism and impulse. Discharged in May, 1932, with partial insight. Recovery completed in home surroundings; she has remained well since.

CONCLUSIONS

1. Thirty-four cases of dementia præcox were given pyrotherapy by injections of sulfosin and dmelcos. 2. Four recovered, 10 showed no improvement, 20 showed some improvement which lasted for varying periods. 3. Comparison of treated and untreated cases over a period of six years showed that no increase in the recovery-rate can be expected from this treatment alone. 4. Pyrotherapy is a useful preliminary to the re-education of schizophrenics by means of organised occupation. 5. The treatment can be repeated in chronic cases when a fresh attempt can be made to obtain the patient's coöperation. 6. Dmelcos has the advantage over sulfosin that there is no painful local reaction. The treatment is both simple and safe.

I am indebted to Dr. E. G. T. Poynder, medical superintendent of the hospital, for his help and suggestions.

MEASUREMENT OF LOSS OF HEARING IN DECIBELS BY MEANS OF TUNING-FORKS

AND DETERMINATION OF HALF-AMPLITUDE-TIME

BY SIR JAMES DUNDAS-GRANT, K.B.E., M.D. Edin.,
F.R.C.S. Eng.

CONSULTING SURGEON TO THE CENTRAL LONDON THROAT AND
EAR HOSPITAL; CONSULTING LARYNGOLOGIST TO THE
CANCER HOSPITAL AND THE HOSPITAL FOR
CONSUMPTION, BROMPTON

THE measurement of hearing-power has lately been discussed in THE LANCET by Prof. Fraser-Harris¹ and by Dr. Phyllis Kerridge.² Prof. Fraser-Harris expresses the opinion that the audiometer will undoubtedly be used universally for all hearing measurements, and it certainly presents attractions which are apt to make us disregard its limitations. At the same time it would be a mistake to overlook the great advantages of tuning-forks such as otologists have long been in the habit of using.

The hearing, when tested by tuning-forks, has usually been expressed in percentages of hearing-power, whereas the audiometer gives it in loss of hearing-power as expressed in losses of sensation-units or "decibels." The advisability of charting defect of hearing in decibels has been stressed by Hallpike.³ It can be effected by means of tuning-forks with the simple calculation described below, and the results can be entered in the well-known audiometer charts, tuning-forks thus taking the place of the audiometer.

For this it is only necessary to know the rate (in seconds) of the dying-down of the amplitude of

vibration of the tuning-fork to one-half, called the "half-amplitude-time" (H-A-T).⁴ If we count the number of seconds for which the sound of the tuning-fork is heard by the normal person after the patient ceases to hear it ("duration-deficit") and divide this by the half-amplitude-time, we obtain the number of half-amplitude-times contained in the duration-deficit. We have then only to multiply this number by 6 (or strictly 6.021) to get the loss in decibels, as one half-amplitude-time is equal approximately to 6 decibels. It can be expressed in the formula:

$$\frac{\text{Duration-deficit}}{\text{Half-amplitude-time}} \times 6 = \text{loss in decibels.}$$

It can also be effected by dividing the duration-deficit by the half-intensity-period and multiplying by 3. The loss of hearing in decibels can then be registered by putting a mark at the appropriate level in each column in the audiometer chart now in vogue (Fig. 1). The half-amplitude-times for the forks I use are the following:—

d.vs.	16	32	64	128	256	512	1024	2048	4096
Pitch	C ₂	C ₁	C	c	c ¹	c ²	c ³	c ⁴	c ⁵
H-A-T	15"	10"	9"	4"	4.7"	2.3"	2.5"	6.5"	4.4"

In order to save calculation at the time of testing we can prepare a chart in the following way, showing the duration-deficits in seconds of each fork corresponding to the losses of hearing for every 10 decibels. The half-amplitude-time (in seconds) of the fork multiplied by 1.66 gives us the duration-deficit for a loss of 10 decibels; we enter this amount (or the nearest whole number) in the appropriate vertical column at the level of 10 decibels; at the level of 20 decibels we put twice that amount, of that of 30 decibels three times the amount, and so forth; the same process is carried out for each of the other forks. Fig. 2 is a chart thus prepared for the set of forks I use or for any other forks with the same H-A-T's.

To use the chart, we note the patient's duration-deficit for each fork and put marks in the corresponding positions on a blank chart, so getting a curve of the same nature as those obtained by testing with the audiometer, the left-hand column showing the amount of loss in decibels.

If it is desired to translate the loss of hearing in

⁴ Dundas-Grant: Jour. Laryng. and Otol., 1929, XLIV., 380, and 1934, XLIX., 233; and the description at the end of this paper.

FIG. 1.—Audiometer chart.

¹ Fraser-Harris, D. F.: THE LANCET, 1934, II., 481.

² Kerridge, P. M. T.: Ibid., 1935, I., 104.

³ Hallpike, C. S.: Jour. Laryng. and Otol., 1933, XLIII., 19.

decibels into the amount per cent. of hearing-power, the following Table (as used by Dr. Phyllis Kerridge) is useful, especially for losses of more than 20 decibels:—

Loss of hearing in decibels.	Percentage of hearing-power.
0	100.0
10	10.0
20	1.0
30	0.1
40	0.01
50	0.001
60	0.0001
70	0.00001
80	0.000001
90	0.0000001
100	0.00000001
110	0.000000001
120	0.0000000001
130	0.00000000001

For lesser losses a table prepared by Miss K. Dickson starts from the datum observed by her that a loss of hearing in seconds equal to the half-amplitude time of the fork (or a loss of 6 decibels) corresponds to a reduction of hearing to 25 per cent. of normal hearing-power; similarly a loss to the extent of half a half-amplitude-time (or 3 decibels) represents 50 per cent. hearing-power. All percentages are

FIG. 2.—Chart showing decibel losses for duration deficits.

mirror (as used for galvanometers) is fixed by means of wax on the outer side of one blade of the tuning-fork close to the tip and a counter-weight on the other blade, as in Lissajou's classical experiment. The fork is fixed in a firm vice and a light is directed on to the mirror from a spot-light or, if more convenient, from the otologist's own bull's-eye lamp, unfrosted and fitted with a metal or cardboard diaphragm having a central perforation $\frac{1}{2}$ mm. in diameter (Fig. 3). The light directed on the mirror is reflected from it, as a luminous dot, on to a sheet of cardboard. When the fork is set in vibration the dot changes into a vertical line (Fig. 3 and Fig. 4A) which shortens more or less rapidly, the time required for it to shorten from any length to half that length (half-amplitude-time) being ascertained by means of a stopwatch. Any definite "waxing and waning" of the amplitude would

FIG. 3.—Lamp, vibrating fork with concave mirror and reflection of light on to scale.

given to the nearest whole number, and other numbers can be interpolated without any considerable degree of error.

Loss of hearing in—		Percentage of hearing-power:
Half-amplitude times.	Decibels.	
$\frac{1}{4}$	0.75	83-84
$\frac{1}{2}$	1.5	71
$\frac{3}{4}$	3.0	50
1	6.0	25
$1\frac{1}{4}$	9.0	12-13
$1\frac{1}{2}$	12.0	6
$1\frac{3}{4}$	15.0	3
2	18.0	2
$2\frac{1}{4}$	21.0	1

Determination of half-amplitude-time.—For forks ranging from 16 to 1024 cycles per second the diminution in amplitude to one-half may be observed by means of the microscope, but also by my simple optical method. The measurement is facilitated by the use of my "converging line gauge."

For the optical reflection method, a small concave

suggest that the counter-weighting was inaccurately balanced.

For the converging line gauge, two lines meeting at a point are ruled on the cardboard and these are

FIG. 4.—Converging Line Gauge.—(a) Vertical luminous line before start of counting seconds. (b) The same when starting the count. (c) The same when stopping the count, i.e., at half-amplitude.

crossed by vertical ones, say, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, and 1 in. in length. The board is placed so that the vertical luminous line lies over one of the longer lines on the gauge, say, the one measuring 1 in. (Fig. 4b); then the stop-watch is started, and, when the line has diminished to $\frac{1}{4}$ in. exactly (measuring by the centre of the rounded "knob" at each end) the board having been moved along until the bright line falls on the $\frac{1}{2}$ in. line, the watch is stopped and thus the "half-amplitude-time" is ascertained. (Fig. 4c). Large amplitudes should be avoided as the law of isochronous vibration applies strictly only to small ones. It is well to repeat the process several times and take the average, using, when possible, lines of different length (say 1 in. to $\frac{1}{4}$ in. and $\frac{1}{2}$ in. to $\frac{1}{4}$ in.).

For the highest pitched forks, 2048 and 4096, another method is required. The observer stands with his ear at say, 10 feet, or the furthest distance at which the sound can be distinctly heard, from the vibrating fork and then "sidles" towards it, keeping the loudness at the same degree till he is 5 feet or half the original distance from it. The number of seconds required for this gives the half-amplitude-time, as described and proved in 1929.⁵ This "sidling" method is inapplicable to low-pitched tuning-forks, as they cannot be heard at a sufficiently great distance, but it can be used for 512 and 1024 which, along with 2048, are the most important tones for the understanding of speech. This experiment should be made in conditions as nearly as possible approaching to the open air.

Apart from other considerations, I venture to believe that the above method of measuring loss of hearing in decibels will meet modern requirements without any very great difficulty.

I gratefully acknowledge much valuable guidance from Prof. E. N. Andrade, Mr. R. T. Beatty, D.Sc., and Mr. W. V. Mayneord, D.Sc.

WEIL'S DISEASE IN A SEWER-WORKER

By JAMES MAXWELL, M.D., F.R.C.P. Lond.

ACTING ASSISTANT DIRECTOR OF THE MEDICAL PROFESSORIAL UNIT, ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO THE ROYAL CHEST HOSPITAL, LONDON

CASES of spirochaetosis ictero-haemorrhagica are being reported in considerable numbers on the continent and in the Far East, including Australia. In this country several series have recently been published which suggest that the disease is not so rare as has hitherto been believed and that it is indeed not uncommon in people who work in wet, rat-infested surroundings. The most recent are those of Davidson and his co-workers,¹ who described 19 cases from Aberdeen, chiefly among fish-handlers, and Fairley,² who described 10 which had occurred among sewer-workers in London within twelve years. Alston³ later described further cases occurring in London sewer-workers and reported the isolation of *L. ictero-haemorrhagiae* from slime in London sewers. Swan and McKeon⁴ noted a hitherto unsuspected source of infection in certain coal-mines in Northumberland and Durham, and recorded 12 cases in miners. In addition, single cases have been described by Willoughby and Shera⁵ in a girl, the cause of the condition not being recognised, by Wolstencroft⁶ in a canal-worker in Hertfordshire, and by Halsted⁷ in a sewer-worker in London. Quite recently

Alston and Brown⁸ have discussed the occupational incidence in this country and have suggested the possibility of prophylactic inoculation in those exposed to the risk of infection.

It seems desirable, therefore, to record sporadic cases as they occur and the following report is submitted because the clue to the real diagnosis was only given when the occupation of the patient was taken into consideration.

A sewerman, aged 44, working in London, came to the out-patients' department at St. Bartholomew's Hospital on May 21st, 1935, complaining of jaundice. On the 13th there had been a sudden onset of pains in the legs, the back, the shoulders, and the head. He felt ill and was slightly feverish, and a small herpetic patch appeared on the lip. He remained in bed and two days later he became jaundiced; the urine was dark and the motions pale. Next day the jaundice increased but the pains and general symptoms were less, and from that time he gradually improved. He was sent to hospital for advice on the eighth day of the disease.

He was found to be moderately jaundiced, there was herpes on the lower lip, and the liver was just palpable but not tender. No other abnormality was discovered. The urine contained a moderate quantity of bile pigment but no bile salts. At no time during the illness had there been any haemorrhage or petechiae, and in fact he does not appear to have been very ill. The only features distinguishing this from an ordinary case of catarrhal jaundice were the sudden onset with pains and fever which had been regarded as suggestive of influenza. Nevertheless in view of the occupation a tentative diagnosis of Weil's disease was made and the patient was admitted for investigation. At that time he was afebrile, with the bradycardia commonly found in cases of jaundice. The Wassermann reaction was negative and the van den Bergh test gave a direct positive result and an indirect reading of eight units of bilirubin. The blood count showed: red cells, 3,900,000 per c.mm.; white cells, 6600 per c.mm.; haemoglobin, 90 per cent.; differential count normal.

The serum was submitted to Major H. C. Brown, of the Wellcome Bureau, who reported on May 24th that there was agglutination of *Leptospira ictero-haemorrhagiae* to a maximum titre of 1 in 1000. The adhesion test was also positive. The urine was repeatedly examined by Dr. L. P. Garrod who was unable to find any leptospirae on May 23rd, but who found typical organisms on May 29th and 30th. On June 3rd considerable numbers of motionless leptospirae were reported; on June 7th there were numerous leptospirae; on June 13th there were small numbers of actively motile leptospirae; and on June 24th no organisms could be detected. It would appear that these organisms are much more readily demonstrated in an alkaline urine, and accordingly the patient was put on sufficient doses of potassium citrate from the time of his admission.

Dr. Garrod also inoculated several guinea-pigs with samples of blood and urinary deposit on May 29th and these died on June 7th with typical Weil's disease, the organisms being demonstrated in large numbers in the liver.

The subsequent clinical course was uneventful. The jaundice had completely disappeared by the middle of June and the patient was kept in hospital until the urine should become clear of organisms. He was discharged completely recovered on June 26th. With the exception of the potassium citrate already mentioned no medicinal or other treatment was given.

The result of the pathological tests proves beyond doubt that the patient was suffering from Weil's disease, yet the clinical features of the condition were such that a diagnosis of catarrhal jaundice would have appeared justifiable if a clue had not been given by the consideration of the occupation of the patient. This illustrates the value in appropriate cases of the special methods of investigation which are now at our disposal, and it emphasises the fact that jaundice of doubtful origin occurring in a patient who might have come in contact with material infected by rats

⁵ Dundas-Grant: Jour. Laryng. and Otol., 1929, xlv., 380.

should be submitted to examination by these methods. The technique of the agglutination and adhesion tests has been recently described by Brown,⁹ who states that a positive agglutination may be found on the sixth day of the disease and that, with the adhesion test, the result is certainly well marked at the end of the second week and possibly earlier. In the present case the agglutination test was positive to a high titre and the adhesion test was also positive on the ninth day of the disease. A further interesting point about the case was the comparative ease with which the organisms could be demonstrated in a centrifuged deposit after the urine had been made alkaline.

A question arose as to when it would be safe for the patient to be allowed to leave hospital. Comparatively little is yet known of the infectivity of the disease amongst humans, but the patient was kept in hospital until the urine was reported as being free from organisms. This subject has been considered by Cotter and Savers,¹⁰ who conclude that carriers are probably not important in spreading the disease.

I wish to thank Major Brown of the Wellcome Bureau for his reports upon serological tests in this case.

LEPTOSPIRAL INFECTION FROM A STREAM

By A. VICTOR NEALE, M.D. Birm., M.R.C.P. Lond.

PHYSICIAN TO OUT-PATIENTS, CHILDREN'S HOSPITAL, AND ASSISTANT PHYSICIAN, QUEEN'S HOSPITAL, BIRMINGHAM

INFECTION with *Leptospira ictero-hæmorrhagiae* is now regarded as a possible diagnosis in any case of acute febrile disease associated with jaundice. Several writers have reported clinical and laboratory observations on the disorder. Among them Alston^{1,2} has recently recorded important facts concerning the infection in sewer-workers in London, and the close association of the disease with rats is now firmly established. Water, slime, &c., to which rats have access, may be found to be infected with the leptospira, and probably certain colonies of rats are a source of constant danger in this respect. There is no definite knowledge concerning the extent of leptospiral infection or carriers in the rat population, but it must be regarded as an important aspect of the "rat problem." Alston brings evidence to show that human infection may be obtained by inhalation of infected droplets of slime or by way of the alimentary tract through the drinking of contaminated water. The possibility of the germ entering the body through skin abrasions has also been considered by Alston.

Laboratory methods in the diagnosis of the disease have been elaborated during the past few years

and now there are available definite criteria whereby the diagnosis can be confirmed. Doubtless, as in most bacterial diseases of man, there is a wide clinical range in the degree of leptospiral infection. Possibly mild infection may not be recognised. In fact Alston has given evidence, based on agglutination tests, that this is so among a certain number of sewer-workers. On the other hand, overwhelming infection with profound toxæmia and jaundice may render the disease rapidly fatal. Protective antibodies and agglutinins have been demonstrated in the blood-serum of recovered cases. In regard to the earliest recognition of specific agglutinins in the blood the data seem to be at present insufficient and but in one of Alston's cases a positive serum commencement of clinical infection. Agglutinins probably remain in the circulating blood for a long time, hence it may be possible to utilise serum in recovered cases in the treatment of the active disease in others.

The principal object of this paper is to record a case of severe infection by *L. ictero-hæmorrhagiae* in a young man who had almost certainly swallowed infected water whilst bathing in a stream.

The patient, aged 20, had had no previous illness. During August, 1935, he had spent a camping holiday on a farm and bathed several times in an adjacent stream. He thought he had swallowed some of the water on one occasion. There were many rats in the immediate vicinity. His illness began when he returned home.

A week before admission to hospital he was taken suddenly ill with headache, vomiting, and fever. Temperature 103° F. Two days later jaundice developed and became progressively worse. Albuminuria and passage of blood in the stools occurred within the next two days. The fever began to decline but the jaundice continued and became deeper. No vomiting of blood and no hæmaturia. On admission to hospital on August 21st he appeared gravely ill but quite clear mentally, although at intervals he was very drowsy. There was intense icterus and conjunctival hæmorrhages were visible. Tongue furred but moist. Small hæmorrhagic points on the gums and visceral mucosa. Temperature 101°; pulse-rate, 100; respirations, 20. There was no diarrhoea but one or two pale, loose stools were evacuated daily. The abdomen was slightly distended but not tender. The liver was palpable two inches below the costal margin. The spleen was just palpable. There were petechial hæmorrhages on the back. The urine contained a cloud of albumin and much bile pigment but no blood nor casts. Intermittent vomiting occurred. Blood count showed: red blood-cells, 4,960,000; white blood-cells, 12,000 (polymorphonuclears 78 per cent., lymphocytes 20 per cent., eosinophils 2 per cent.).

In view of the history and clinical picture a diagnosis of Weil's disease was made.

Treatment was chiefly symptomatic. He received six pints of plain fluids daily and liberal quantities of glucose. Intramuscular calcium gluconate was given. Arsenical preparations were withheld in view of the probable severe hepatic damage. The dehydration and severe toxæmia showed much improvement forty-eight hours after admission but the jaundice remained extreme. There was no pruritus. His temperature settled to a normal level and the pulse-rate fell to 60. A few days later the pulse reached a minimum of 50 but returned to 70 on recovery. On August 24th (ten days from the onset) the blood showed a positive biphase van den Bergh test. The urine contained a number of leucocytes and a few hyalogramular casts. No leptospira were seen in examination by dark-ground illumination. Cultural examination of blood was negative, and animal inoculation of the centrifuged deposit of urine gave a negative result.

The patient's progress was very satisfactory, and one week after admission he appeared to be out of danger. The cardiac sounds were better and no further hæmorrhages appeared. The jaundice, however, remained very

¹ Alston, J. M.: THE LANCET, 1935, i., 806.

² Alston, J. M., and Brown, H. C.: Brit. Med. Jour., 1935, ii., 339.

marked; it was, in fact, still detectable four weeks later. The liver diminished to the normal size. The spleen became impalpable. There was at no time any glandular enlargements. In the early stages his tendon reflexes were diminished but neurological examination later gave normal findings. There were no ophthalmoscopic changes.

Three weeks after the onset of the illness Dr. Alston carried out tests with the patient's blood-serum and found that the serum agglutinated *L. ictero-haemorrhagiae* in dilutions up to 1:30,000, thus confirming the clinical diagnosis of leptospiral jaundice. He also, at the same time, examined a specimen of urine but was unable to demonstrate therein any leptospira. It is, however, probable that if daily specimens could have been examined one in the early stage of the disease the infecting organism and id may have been found to be present. The patient finally diffide a complete recovery and is now well.

Clinically this case closely resembles those described as typical of the disease. Intense and rapid toxæmia with high fever, passing on to a deep icterus of obstructive type, and mucosal hæmorrhage, associated with polymorphonuclear leucocytosis, can be regarded as characteristic. Early diagnosis is very desirable in view of possible cross-infection in a ward. Severe cases of acute catarrhal jaundice may bear a superficial resemblance, and where the distinction is doubtful a blood count is helpful, inasmuch as in the catarrhal jaundice there is a relative or absolute lymphocytic response, in contrast to the polymorphonuclear response in true leptospiral infection. In Alston's cases the total leucocytes ranged from 15,000 to 20,000 per c.mm. The danger of rapid hepatic and renal failure is apparent in leptospiral jaundice, and it appears reasonable to attempt to combat this by an adequate and ample supply of glucose, by the intravenous route if necessary. The severe vomiting, so often seen in the disease, adds an extra danger to the patient by way of dehydration and further visceral impairment. The very high blood-urea reported in some cases is interesting in this respect. It is hoped that these general measures in treatment, combined with the possible use of blood or serum from recovered cases, will lower the mortality-rate of this potentially serious disease. In the case here recorded it must be granted that the patient was fortunate in possessing such a remarkable power of producing antibodies to the leptospira. As above stated, he developed an agglutination titre of 1:30,000.

ONCHOCERCIASIS IN ENGLAND

By H. A. OSBORN, D.M. Oxon., D.P.H.
SOUTHERN GROUP PATHOLOGIST, LIVERPOOL

ONCHOCERCIASIS a disease caused by a species of filaria, is endemic in some tropical regions of Central America and West Africa, but no sporadic cases have hitherto been described in this country. The development of rapid transport of cargoes between warm and temperate lands may lead, however, to the occurrence of isolated cases in the temperate zone.

In August, 1933, a man, aged 62, was admitted to Mill Road Infirmary, Liverpool, suffering from hydrocele. A scrotal swelling had been present for five years, but during the past six months discomfort had been experienced owing to the rapid increase in the size of the hydrocele. Orchidectomy was performed by the late Mr. C. O. Davies and some cystic fibrous tissue was removed, and routine sections of this fibrous tissue showed the presence of a microfilaria 240 μ by 7 μ . The larva was sheathless and

the nuclei did not extend to the tip of the tail, the most distal nuclei of the tail being oval in shape. Filaria were not found in the blood, nor was there any eosinophilia, and a diagnosis of onchocerciasis was therefore made.

Three days after the operation there was swelling of the scrotum with cedema of the wound; it was thought that this might have been due to the larva, but the cedema rapidly subsided and the patient was discharged. The patient was seen later and the scar was normal. According to Sharp¹ hydroceles due to onchocerciasis are not very amenable to surgical treatment as they are apt to result in prolonged suppuration, but in this case the wound healed by first intention.

The patient was closely questioned, but he insisted that he had lived all his life in this country and had, in fact, never left Liverpool; the infection must therefore have been contracted in Liverpool. According to Strong² the human carrier constitutes the important means of transporting onchocerciasis to distant localities, but the infected "black-fly" (simulium) is the means of transmission of the disease from man to man in regions where it is endemic. It seems likely, however, that this patient, who was a cotton porter, working at the docks, was bitten by an infected black-fly brought to this country on a cargo vessel. It has been estimated by Bequaert³ that the biting black-fly, the female, lives for several weeks, although it was difficult to keep them alive in captivity for more than a few days.

If this theory of infection is correct this case is an exception to Strong's rule; but another possibility must be considered. There are several species of black-fly to be found in this country, and they have been described by Edwards,³ though it is not known if they are capable of acting as vectors. As far as is known there are no infected black-fly in this country.

This question has arisen in the United States of America; Johnstone and Larsen⁴ have pointed out that onchocerciasis has a northward drift in America, and that the possibility of the simuliids in the United States acting as vectors of the disease should be investigated. The situation of the lesion pointed to the importation of a species of black-fly from West Africa, as the American fly usually attacks the head, and the scalp is the common site of the nodule; Sharp¹ described several cases of hydrocele in his African series, so that probably the West African species, *S. damnosum*, was responsible for the infection in Liverpool.

I am indebted to Dr. W. M. Frazer, medical officer of health for Liverpool, for permission to publish this case.

LONDON JEWISH HOSPITAL.—An appeal for £60,000 has been launched for this institution with the approval of King Edward's Hospital Fund. It was founded some fifteen years ago as an out-patients' department and is now a general hospital with 100 beds. Over 28 per cent. of the patients are not of the Jewish faith. A new nurses' home is a necessity as the present arrangements for their housing, recreation, and instruction are inadequate. A new home will release wards, which at present are being used as cubicles for the nurses, for in-patients of whom there is a long waiting-list.

ROYAL SOCIETY OF MEDICINE

SECTION OF EPIDEMIOLOGY

IN his presidential address to this section on Oct. 25th Surgeon-Captain S. F. DUDLEY, R.N., considered the

Biological Approach to the Study of Epidemiology

Epidemiology, he said, can be studied with advantage as that branch of academic biology which deals with the physiological reactions of parasitic and host groups of organisms to each other. After paying a tribute to the late Theobald Smith as one of the greatest investigators of host-parasite relationships which are the foundation on which scientific epidemiology is built, Dr. Dudley stated that "natural selection" was the fundamental theory in biology and if the principle was accepted with all its implications then all biological hypotheses, including speculations on the cause of epidemiological phenomena, must harmonise with the principle of natural selection or be discarded as false. Immunity or resistance to parasitic infection was so variable among members of the same race or species that immunity characters must be represented by many genes in the hereditary mechanism. Insuperable difficulties were often encountered when attempts were made to distinguish inherited or natural immunity from acquired immunity. These difficulties were not rendered any easier when it was realised that immunisability, the potentiality of acquiring immunity, and the durability or permanence of immunity, were also hereditary characters which could be augmented by experience, that is by contact with specific bacteria or their products. In fact the difficulty of deciding the relative importance of nature and nurture was as great to the immunologist as to the eugenicist and social worker. He illustrated these points with the supposed racial immunity of the negro to diphtheria in Africa, where clinical diphtheria is rarely seen and the Schick immunity very high; whereas the negro in the United States exhibits little difference from the European as regards Schick immunity and diphtheria mortality.

Modern work on gene-mutation mutation rates and X ray mutations suggests to Dr. Dudley that parasitic variability is a more frequent cause of epidemics and variations in the clinical pictures of disease than most bacteriologists have hitherto been prepared to admit. The multitude of types and varieties into which all bacterial species are now split probably, he said, arose comparatively recently as mutants of a common ancestor; it was likely that many of these parasitic mutants cropped up over and over again and were selected for survival at the moment when the conditions were propitious for their dissemination throughout the host herd. In illustration of this he described some peculiar changes in the relative prevalence of the variants of diphtheria bacilli, virulent and avirulent, "mitis," "intermediate," and "gravis," at different times and places. He also gave examples showing how under apparently identical conditions the carrier rate from meningococci could vary from 5 to 50 per cent. In contrast to the sexual metazoa, Dr. Dudley continued, the doctrine that acquired characters are never inherited is not strictly true when applied to unicellular organisms, because new inheritable characters can be impressed on certain protozoa

and bacteria by their environment. Trypanosomes can be trained to tolerate therapeutic drugs in doses that, previous to their education, would have been immediately fatal, and the trypanosome will retain this drug-resistant character even after passage through the tsetse fly. Parasites, he said, are highly specialised in one character, namely, "host specificity," that is, with numerous exceptions each host animal has its own parasitic flora and fauna adapted to that species and no other. Moreover parasites are only adapted to living hosts and cannot compete with the putrefactive and saprophytic organisms which invade their host after death. Therefore the popular fear of getting disease from animals and corpses has little foundation in fact.

Nevertheless, it is not improbable that certain outbreaks of disease may be due to aberrant parasites who have strayed out of their normal hosts in an endeavour to adapt themselves to a new habitat. Disease and epidemics are not the striking phenomena in wild untouched nature that they are among man and his domestic animals and plants. In wild nature the organisms are in equilibrium with each other and their environment; which means that the average number of each species is more or less constant. The environment is supporting the maximum number of each species which is possible under the prevailing conditions. The natural fecundity of the species is balanced against the pressure of the environment and there are no vacant places left for the further multiplication of the species. When an animal is increasing in numbers there must be vacant places awaiting occupation in its environment, the struggle for existence is less severe and natural selection less active so that under such circumstances unfit members of the species may be able to escape elimination. There are still many vacant places in man's environment, and in consequence there are still as many left for his parasites. Man has to compete with no other species but his own, and his parasites whose destiny is of course bound up in that of their human hosts. This, said Dr. Dudley, is one reason why man can still multiply and at the same time carry a heavier handicap of disease than any other species; but the chief reason why disease should be the special prerogative of *Homo sapiens* is that he is for ever altering and interfering with his own (and therefore his parasites') environment, and the latter never have time to adapt themselves to one environment before they find themselves in another.

SECTION OF PHYSICAL MEDICINE

AT a meeting of this section on Oct. 25th Dr. C. B. HEALD read a presidential address entitled

Electrotherapy 1910-35

As an illustration of the great development of electrotherapy in the present reign, he showed the inventory of apparatus—four pieces—at the Royal Free Hospital in 1910, the much longer list of 1920, and the imposing equipment of the present day. The number of treatments given every year had risen from 10,000 to 80,000. Dealing with the various forms of therapeutic electric current, he showed oscillographic tracings illustrating the improvement in the type of impulse from the early faradic coils to the latest developments of the rhythmic myotroph. He devoted a large part of his address to the various methods of heat treatment which had been introduced during the

Dr. Robert Hellig M.D.

E. J. A. Medical College

reign for combating shock, inducing sweating, or artificially raising the temperature of the body. The earliest device was a radiant heat shock cradle, containing twelve carbon filament bulbs. This had given fairly good results but improvements had been made by using elements which generated far less light and more heat. He had lately made experiments to compare the heat generated by the various types of apparatus and the pyrexia produced. The apparatus investigated had been the old type radiant heat cradle, the London County Council model shock cradle, the infra-red tunnel of the British Red Cross Society, and an electric blanket and short-wave apparatus of two types, the inductotherm and Wilde's pyretic bath. The British Red Cross Society used a heating element consisting of a self-insulated wire in a quartz tube. The infra-red rays were greater and the light less than in the old cradle and the clinical results were better; in particular this cradle relieved periarticular muscular spasm.

The effects of heat treatment differed widely according to the mixture of the rays, the site of entry, the intensity of the beam, and its duration. Tests showed that once the heat-regulating mechanism of the body was altered, either by a kind of breakdown or a readjustment on a new plane, very little energy was required to maintain the general body temperature above normal. Treatment with a radiant heat bath should not be started until at least two hours after a light fluid meal, or nausea and other distressing symptoms might occur. The patient's toleration and comfort were enhanced if he drank large quantities of glucose and saline fluid flavoured with lemon. The concentration of saline must be 0.2 per cent., which was not a pleasant drink but which was absolutely essential to replace the salt lost in excessive sweating.

The conditions of the experiments had been made as standard as possible. When the L.C.C. cradle had first been tested at the Royal Free Hospital with a dummy on the bed the temperature had risen rapidly to a very high level and large differences of temperature were observable on the surface. On the other hand, when a patient was in the bath the temperature on the top of the blanket became stable at 152° F. and the skin temperature under the blanket became stable at 116° F. This illustrated the powerful thermostatic effect of the patient. A radiant heat bath of this type could rapidly produce sweating and rise of temperature with full power, but so intensive a treatment could not be good for shock or safe for prolonged pyrexia. When six lamps were used instead of twelve the temperature, pulse-rate, and blood pressure were not affected while the skin temperature was slightly raised. The electrical blanket provided an efficient and not uncomfortable method of transferring heat energy to the patient.

Dr. Heald referred to the lecture delivered by Dr. C. A. Neymann before the Royal Society of Medicine in the present year, in which the American worker pointed out the advantages of securing hyperpyrexia by high-frequency current: ordinary diathermy, short-wave diathermy, and inductothermy. Dr. Heald showed a chart of a typical response to diathermy from both hands to both feet; temperature, pulse-rate, and respiration-rate were all raised and sweating was profuse. He had included in his experiments a test of short-wave apparatus and inductothermy and had, like Dr. Neymann, concluded that inductothermy was probably the best of these methods. It differed in that the current was not passed directly through the patient but through a

coil of insulated wire laid upon the pack in which he was wrapped: usually an airtight bag with a zip fastener. The generator was said to have an output of 950 watts, and the very rapid expansion and contraction of the electric field in the wire caused eddy currents within the conducting parts of the body—the fluids, muscles, and nerves. A feature of inductothermy treatment was that the feeling of warmth it produced remained for several hours after treatment was discontinued. On the whole, the electrical methods were more comfortable than the application of rays.

Dr. Heald commented on the difference between the American and the English reports on the white cell counts during treatment. While the white cells were generally reported by English workers to fall, the Americans showed a great increase. It was possible that the Americans had not allowed, as he had, for dehydration. The count was an invaluable control, for a rapid fall was a signal to stop treatment.

At the close of his address, Dr. Heald gave a demonstration in support of his belief that infra-red rays actually penetrated the patient's body and exerted an effect upon its constituents. A photo-electric cell was connected to a Cossor Robertson electrocardiograph of the latest type, and the sensitive bridge of the cell was completely covered with a substantial piece of meat; but when infra-red rays were directed at the meat the oscillograph showed a vigorous response. It showed a similar response when Dr. Heald irradiated the meat with a Kromayer lamp fitted with a filter which cut out all visible rays. He took this result to indicate that, besides the ultra-violet rays which it is constructed to emit, the Kromayer lamp also emits an isolated band of infra-red rays and that its therapeutic effects may be due in considerable measure to this band—a sharply defined and comparatively narrow band being known to have a greater effect than the same band grading off into higher and lower wave-lengths.

MEDICAL SOCIETY OF LONDON

At a meeting of this society on Oct. 28th, with Prof. G. E. GASK, the president, in the chair, a discussion on

Electrical Injuries

was opened by Dr. MACDONALD CRITCHLEY. In each year, he said, the number of fatalities from electrocution in England and Wales was 50 or 60, but there must also be a very large number of minor and major injuries both in industry and in the home. In Germany the number of deaths was higher—probably about 400 annually—and in the United States it was 700 to 800. In this country the consumption of electricity was four times what it was in 1912, but the mortality in 1934 was lower. Several factors determined the type and severity of the accident, and the first was voltage. In general terms, the higher the voltage the greater the danger; but 45 volts had been known to kill a person, and 60 certainly would do so. Deaths from contact with the ordinary electric lighting main were very common; on the other hand, cases were on record in which people had touched a main and received 132,000 volts and still survived. The next factor was amperage: it was the amount of current passing through the person which was important rather than the pressure; 20 to 30 amperes was an unpleasant strength, 80 to 90 was dangerous. The type of

current was also important; volt for volt, the alternating current was much more dangerous than the direct, and that fact was borne out by the Home Office figures, particularly up to a voltage of 250. The next important factor was the resistance of the tissues. Skin, especially when dry, was highly resistant to the electric current; sweating reduced its resistance 12 times and immersion in water 25 times. The best conductor of electricity in the human economy was the cerebro-spinal fluid, and it was closely followed by the blood, the muscles, and the liver. The nervous system was resistant; it had been found that the sciatic nerve had eight times the resistance of Atlantic cable. A further important factor was the duration of the current's passage; momentary contact with a heavy charge might be innocuous, but the longer the duration the more the tissue resistance dropped.

A person receiving a strong electric shock almost always experienced highly unpleasant pain; survivors of such shock described an agonising pain throughout the body. Many complained of deafness and tinnitus if the shock continued; often they were completely blind, and some described actual hallucinations—balls of fire, a brilliant setting sun, balls or flashes of light, and moons. Some spoke of a feeling of a shrinkage of the body, and a loss of time-sense, so that a contact of five seconds seemed like ten minutes. In some cases there seemed to have been a notable absence of pain, though other sensations were felt. Unconsciousness did not necessarily follow, but might do so. It might result immediately from pain, or the person might fall to the ground soon after receiving the shock and remain unconscious for minutes, hours, or a day or so; during this period there might be motor agitation, convulsion, twitching, tremor, and a sense of increased intracranial pressure. The tension of the cerebro-spinal fluid might be raised, and it might contain blood; some stated that its temperature was raised. As in concussion injuries, there might be retrograde amnesia—e.g., in the case of a boy who climbed up a pylon, made contact, fell to the ground, and, when he reached home, asked for his midday meal, although he had already had both dinner and tea. Another type of unconsciousness was that which came on after an interval of, perhaps, some hours; this was due to increasing cerebral oedema.

Electric burns were abnormally deep; secondly, they tended to spread in the first few days after the shock, and this might be dangerous because of the liability to reactionary hæmorrhage, especially as one effect of the shock was to make the blood-vessels of the locality unusually friable. In Vienna this danger was so well recognised that means of dealing with sudden hæmorrhages from this cause were always kept ready in the hospitals. In comparison with a burn from an ordinary fire, the surrounding erythema was much more limited. One authority stated that electric burns were painless, but Dr. Critchley did not agree, though the explanation that the pain might be due to the burning of the clothing was a possible one. Another statement which he did not accept was that electric burns were sterile. They healed rapidly, and the resultant scar was a good one, mostly free of contractures, it was said; but he had seen bad deformities follow. The points at which the current entered and left the body were usually indicated by rounded greyish areas, which were painless. The patients showed a peculiar metalisation of the skin, an appearance much resembling morning frost on a pane of glass, due to

minute depositions of copper in the dermis. In severe cases the burns might amount to gigantic tissue necrosis; indeed, a whole limb might be almost amputated by the electric current.

Bony injuries caused by electricity were important though less common than other forms. When a current passed through a long bone it produced a longitudinal fracture, without fragmentation, but the apposition was so good and the fissure so narrow, that it was not recognised, even by radiography. As pain persisted, another radiogram was taken, and by this time the parts fractured were not in such close apposition, and osteomyelitis, and perhaps sequestration, followed. A second type was a fracture or fracture-dislocation due to direct muscle violence. A third was injury of the skull; this was specially apt to occur when the skull formed one of the points of contact. In one such case a man was picked up unconscious and all that was seen on his head was a slight pimply swelling, with a mark on the sole of the foot where the current had apparently left the body. The "pimple" subsequently developed and formed an extensive ulcer, which was sharply punched out, with much thinning of the underlying skull.

The remote effects of electric shock were rarities but often missed. They were either ocular or neurological. The ocular were two only: optic atrophy and cataract. The neurological were much more complex, and might consist of organic disease of the spinal cord or brain. It must also be realised that organic neurological diseases could be precipitated by electric shock—e.g., disseminated sclerosis, parkinsonism, cerebral tumour, myasthenia gravis. Cerebral complications were not very common; they took the form of focal lesions—i.e., hæmorrhages, softenings, or abscesses. There were records of cases in which the onset of epilepsy was ascribed to an electric shock. The post-concussional syndrome was also seen in these cases, especially those in which the head formed the point of electrical contact. Such a patient might draw compensation for years because of giddiness, headache, and the like. Much more characteristic were the complications in the spinal cord. Here the picture was like that of amyotrophic lateral sclerosis; there was a wasting of the muscles of the hand, which spread up the arm, and then developed in the other hand; later the legs became affected, and there was pyramidal involvement, with double extensor plantar responses. There seemed to be a close association between the electric shock and the onset of spinal atrophy, and the term "spinal atrophic palsy" was used in this connexion. Peripheral nerve lesions were uncommon after shock, but they did occur; there might be palsy of either median or ulnar nerve.

Psychological disorders often started after severe electrocution; or they might be modified—and even cured—by the shock. Psychoses had been relieved, and in some cases cured, by electric shock, just as by lightning stroke; a boy in an asylum suffering from dementia præcox climbed up a pylon and after recovering from the immediate shock was mentally much better. Hysteria was very common after electric shock, as after lightning. A striking case was that of a man in Berlin who fell on to an electric line so that his arm came into contact with the live rail. His arm was paralysed and apparently insensible to touch, and it remained inert at his side for a long time. But later it was clearly proved that there was no current in the rail at the time of the fall.

The actual cause of death remained a problem. One theory was that it resulted from ventricular

fibrillation; another that it was due to medullary inhibition of respiration. Dr. Critchley thought it probable that both were correct. Books on ambulance work still insisted that if necessary artificial respiration should be continued for hours, though it was established that the brain cells could not revive if deprived of circulation for 20 to 30 minutes. But as respiration and circulation, though very feeble and not detectable, might still be carried on, it was well not to alter the ambulance instructions. As regards prevention, Dr. Critchley paid a tribute to the adequacy and thoroughness of the Home Office Regulations, and the energy with which failure to control industrial apparatus was punished. This control, however, did not extend to home accidents, and there the need seemed to be proper education, especially about the risks of worn flex for ironing or lighting.

Mr. ERIC PEARCE GOULD said that for judicial electrocution at Sing Sing Prison a current of 22,000 volts was used, and it was kept on until the flesh began to burn, a matter of some 17 seconds. If the stethoscope showed that the heart had not ceased to beat, the doctor signalled for a second discharge, but this was very rarely necessary. He gathered that there was a good deal of pulping of the brain immediately subjacent to the head injury. He had seen some cases of electrically caused injury on the Southern Railway in the old days. It was a different story now with the third conductor rail, because the voltage there was only 650 of direct current. Of 2274 accidents on that railway in 1934, the total number of electrical injuries was 38, and only two of these were fatal, both the victims being children (aged 6 and 12) who had strayed on to the line. The average period of incapacity following the injuries was 7 weeks 2 days. That surprised him, because among those who had sustained electrical accidents he had noted a definite distaste to resume the work, from fear of a recurrence of the experience. His impression was that burns caused by electricity were not as painful as those caused in other ways. Some healed with scars which would be recognised as those following burns, but in some cases, despite the extent of the burn, there was surprisingly little scarring.

Mr. ZACHARY COPE related cases of severe lightning burns and electric shock which he had seen.—Commander T. N. D'ARCY described a case in which an electric shock from a main was carried along a stream of urine.—Mr. A. SIMPSON-SMITH gave a short description of legal electrocution carried out in Massachusetts, and Dr. CRITCHLEY briefly replied.

LIVERPOOL MEDICAL INSTITUTION

A MEETING of this institution held on Oct. 17th, with Dr. C. O. STALLYBRASS, the president, in the chair, was devoted to a discussion on

Coronary Thrombosis

Dr. E. WYN JONES described the coronary circulation as demonstrated by radiography. He laid emphasis on the age changes in the vessels and especially on the development of anastomotic channels with increasing age.

Dr. H. WALLACE JONES outlined the clinical aspects of coronary thrombosis. Only during the last few years, he said, had it been realised that most patients recover from the attack. The illness fell into two stages: (1) the initial anginal attack, and (2) the

evidence of myocardial infarction and damage. During the attack important features were pain, vomiting, air-swallowing, fall in blood pressure, and distant heart sounds. The subsequent signs included pericardial friction, congestive failure, pyrexia, leucocytosis, emboli, and abnormal rhythms. Atypical forms of the condition included the painless, ingravescient, and abdominal types.

Dr. E. NOBLE CHAMBERLAIN, speaking of the electrocardiographic changes, said that one of their most important features was frequent variation within a comparatively short period. Lack of knowledge meant that the treatment was not yet on a fully satisfactory basis. Morphine should be used in doses sufficient to relieve the pain, which often meant giving as much as 1 grain within two hours of the onset. The usual treatment of shock was indicated in cases where collapse was conspicuous, and if the fall of blood pressure was extreme adrenaline or ephedrine might be helpful. Digitalis should be reserved for cases in which definite signs of congestive heart failure develop a few days after the attack of coronary thrombosis, and those complicated by auricular fibrillation. Oxygen—preferably given in an oxygen tent—was useful in cases where cyanosis and dyspnoea were prominent. In the subsequent treatment the most important point was the restriction of undue mental or physical exertion, the treatment of the angina of effort which usually followed, and the enforcement of rest in cases where recurrent cardiac pain occurred without effort.

Prof. J. H. DIBLE described coronary thrombosis as the last act in the long drawn out drama of coronary atheroma—a disease which in some people affected the coronary arteries much more than others. By the time the disease had advanced to the stage of thrombosis the chronic ischaemia had usually led to a good deal of focal destruction of the myocardium which had a high oxygen-consumption and when actively contracting demanded 1-1½ litres of blood per minute. The thrombosis was followed by a cardiac infarct and a new set of conditions arose. The process of organisation began immediately, whilst pericarditis developed on the surface and mural thrombosis frequently in the interior of the ventricles. Both systemic and pulmonary emboli were possible consequences of the latter whilst autolytic softening of the infarct might occasionally result in cardiac rupture. When the organisation of the infarct was complete, it left a fibrous scar in the ventricular wall which might become the site of a cardiac aneurysm.

The PRESIDENT said he would add a word on how not to diagnose coronary thrombosis. Sudden death in a person not known to have suffered from coronary disease did not justify this diagnosis.

Prof. JOHN HAY spoke of the importance of the atypical manifestations. Correct diagnosis was necessary because prolonged treatment was advisable after even a minimal thrombosis. The usual symptoms of pain and collapse might be present but mild, or the pain might be absent or negligible, with some other feature dominating the picture—e.g., apprehension, much dyspnoea, congestive cardiac failure, a pathological rhythm, or symptoms suggesting an acute and serious abdominal lesion. The proportion of cases in which pain was absent was far higher than was generally appreciated.

Dr. I. HARRIS said it was risky to rely on electrocardiographic evidence alone, because often electrocardiograms suggested coronary thrombosis when no clinical evidence of it could be found. The condition

was a common complication of high blood pressure. With a high blood pressure the pressure in the coronary circulation ought to be enormously increased; and yet it was known that the factor which favours thrombosis is a slow and feeble circulation. This was a significant fact. Dr. Harris emphasised the importance of systolic pressure readings. The pressure was low after the attack, and a rise during convalescence was a favourable sign. A fall was always an indication for prompt action—e.g., putting the patient to bed and possibly administering cardiac tonics. He found strophanthin much more useful than digitalis in these cases. After the acute stage of coronary thrombosis was over graduated exercise was beneficial in suitable cases.

Dr. F. B. JULIAN said that as digitalis was likely to cause a rise of pressure in the coronary arteries, and a raised pressure was one of the factors in the production of coronary thrombosis, caution was perhaps called for in the use of digitalis in the senile type of auricular fibrillation.

Dr. R. C. WEBSTER referred to syphilis as an ætiological factor. He asked whether the clinical syndrome ascribed to coronary thrombosis might not occur, in the absence of actual thrombosis, in cases of defective coronary circulation.

MANCHESTER MEDICAL SOCIETY

At a meeting of this society on Oct. 2nd, Dr. R. G. GORDON, of Bath, read a paper on

Osteo-arthritis and its Concomitants

Osteo-arthritis, he said, is too often confused with other diseases included under the generic term of chronic rheumatism, and not enough thought is given to the treatment of the individual case. Osteo-arthritis should be distinguished from ossification of muscular, ligamentous, and fascial insertions. It is primarily a degenerative condition, exostoses being compensatory and secondary, and it occurs in joints whose blood-supply is deficient and which have been subject to previous disease, strain, or trauma. Essentially it is a degeneration in the central cartilage, leading to thinning, ribbing, and finally disappearance with exposure of underlying bone. The bony changes consist in formation of exostoses and eburnation of exposed parts; the capsule and ligaments are at first fibrosed but may eventually disappear leading to new muscular attachments.

Symptoms of osteo-arthritis are pain, stiffness, and limitation of movements with deformity in late stages. Pain is due to pressure on exposed bone and muscular spasm. Stiffness and limitation of movement are only occasionally due to exostoses and loose bodies, and generally due to fibrositis, muscle spasm, and fibrosis of the joint capsule. Deformity is due to changes in bony architecture and to new attachments of muscles pulling the bones out of position. Diagnosis can be confirmed only by radiography, but pain, stiffness, limitation of movement, arterial degeneration, and neighbouring fibrositis in an elderly patient should always arouse suspicion. Prognosis though eventually bad should not be too gloomy, since much can be done to stop or delay progress and to remove the concomitant fibrositis.

Treatment is general, local, and adjuvant. General treatment consists of measures to arrest cardiac, renal, and vascular degeneration, especially those which will dilate the capillary bed and promote elimination by skin, kidneys, and bowels. Local

treatment is directed to increasing circulatory efficiency of the joint, relieving pain, and reducing muscular spasm. Protein shock has had a vogue for this purpose, but physical methods especially heat applied to the joint are more useful. No trauma must be applied to the joint; therefore manipulation must be carried out with the greatest care and operation is applicable only to carefully selected cases. Splinting is often very useful, especially the walking calliper in hip and knee cases if the patient can be persuaded to tolerate it. Adjuvant treatment is chiefly directed to the accompanying fibrositis. In the elderly subjects of osteo-arthritis this will consist of the right kind of massage and eliminative methods, chiefly in the form of physical and hydro-therapy. Removal of septic foci will have only a secondary place since both the osteo-arthritis and fibrositis are chiefly due to metabolic changes consequent on vascular degeneration and faulty elimination. Diet in fibrositis and osteo-arthritis is not specific, but is of importance in so far as it may reduce obesity, prevent cardiorenal degeneration, or preserve the patient from metabolic disturbances due to indigestion.

ROYAL ACADEMY OF MEDICINE IN IRELAND

Dr. V. M. SYNGE gave a presidential address to the section of medicine at a meeting held on Oct. 11th, with Dr. A. R. PARSONS in the chair. His subject was

Tendencies in Present-day Medicine

The progress of medicine in the past, he said, is represented more accurately by a series of waves than by a straight line. We cannot tell whether present-day progress is nearing its crest or not, but we do know that the curve is still rising. During the past few decades pathology, bacteriology, biochemistry, and psychotherapy have in turn been to the fore, and we notice here a tendency to move from the more concrete to the less concrete. The mental equipment of the doctor has four elements:

- (a) Inherited and acquired mentality: disciplined thinking power, common sense, and free mental judgment.
- (b) Technical knowledge acquired as a medical student.
- (c) Knowledge gained by practical experience.
- (d) Absorption of new medical methods and discoveries.

His capacity for diagnosis, treatment, and prognosis may be expressed by $a+b+c+d$. As age advances b diminishes, c increases, a is constant, d varies greatly and depends in some measure upon a . Good secondary education is necessary if the value of a is to be maintained; b is tending to become of less practical value as the medical curriculum is lagging more and more behind modern medical knowledge. This is likely to continue as long as the dominant idea in the alteration of medical education is to add to the curriculum without at the same time eliminating out-of-date material. The value of d depends not only upon new discoveries but also upon their accessibility. Research has not produced as much fresh knowledge as it should have. Apparatus and equipment should not be considered of more importance than the researcher himself. Too much research work is done to order, and work done for the sake of publication is often of little value. Medical literature is now unwieldy. Indexes of medical literature are inadequate and not sufficiently international. In the patient's mind, said Dr. Synge, the idea of

magic is being transferred from the doctor to his instruments; but despite the deluge of quack medicines and pseudo-scientific advertisements the patient is gradually advancing in his medical outlook.

Dr. H. F. MOORE said that if facilities for investigation existed in Ireland it would be easy to regain the fame which the Irish medical school had held in the days of Stokes, Corrigan, and Graves. A scheme started by the Academy of Medicine had now been adopted by the authorities.

Dr. R. J. ROWLETTE spoke of a reference by the president to team-work. The word "team" could be applied in two different senses which it was important to distinguish. It had first been used for a group of three or four practitioners who had banded themselves together for commercial purposes in running a practice; they had different capacities—surgeon, physician, or other specialist—but they dealt with everything that came their way. On the other hand, the term was often applied to a group of practitioners, each with a separate line of approach, who could be assembled to deal with a particular case. Instead of the team being a fixed group, it was a group assembled for a particular occasion to deal with a particular problem. Such a group could be readily assembled in any university centre, and without such co-operation medicine would be much the poorer; but very little could be said in favour of the team in the narrow commercial sense.

Dr. E. T. FREEMAN referred to the pressure put on the medical profession to use various drugs when they had not even had an opportunity of trying them. A doctor was expected to buy a certain apparatus because his patients, having read newspaper advertisements, expected him to have it.

Dr. W. R. F. COLLIS maintained that Irishmen were really well fitted for research, but had hitherto lacked opportunities. Research was essentially a whole-time job, and there was a need for whole-time research clinicians.

Dr. G. C. DOCKERAY said that there was a tendency to send to the laboratory everything except the patient and the necessary information. He hoped that under the new research scheme technicians would be properly trained, and paid a salary in some degree commensurate with the work they did.

Dr. C. J. MCSWEENEY spoke of the rise of the preventive idea in medicine. Nowadays no child ought to develop diphtheria. Immunisation against scarlet fever was also possible, and other diseases were rapidly coming into the preventable group.

Dr. ALAN THOMPSON considered it unfortunate that the pathologist and the radiologist were so much out of touch with the material with which they had to deal. There was a great opening for the introduction of the pathologist to the hospital wards.

The PRESIDENT in his reply said he thought research laboratories produced relatively little of value in proportion to their number and to the amount of work done in them. Medical students, he believed, were obliged to learn too much anatomy and physiology; they should not be allowed to enter medical schools without some preliminary scientific knowledge. Chemistry and physics were taken so fast that they were not approached in a scientific spirit. A student's mind should be trained so as to enable him to take up facts which would come into force a few years after he was qualified. Medicine should be taught as a dynamic moving subject and not as one which did not change.

REVIEWS AND NOTICES OF BOOKS

A Century of Municipal Progress

1835-1935. Published under the auspices of the National Association of Local Government Officers by George Allen and Unwin, Ltd., London. 1935. Pp. 511. 21s.

"For the average English citizen," said Graham Wallas, "the possibility of health, of happiness, of progress towards the old Greek ideal of 'beautiful goodness' depends on his local government more than any other factor in his environment." Of this, however, the average citizen is unaware; he takes his local government for granted, and is far from realising that the story of how it came to be what it is and what it does for him is of fascinating interest. In this book, which is issued under the auspices of the National Association of Local Government Officers, the story is well told and deserves to be read by all who care for the promotion of good citizenship. The book is the work of seventeen writers, each an outstanding authority on the subject with which he deals: Sir George Newman writes on public health, Sir Josiah Stamp on municipal finance, Sir Frederick Kenyon on municipal museums and art galleries, Sir E. D. Simon on housing and civic planning, and Mr. Herbert Morrison on highways and transportation; and in a brilliant introductory chapter, "Before 1835," Prof. Elie Halévy shows how the English genius for local government found effective expression long before the Municipal Corporations Act was passed a century ago. Mr. L. Hill, general secretary of the N.A.L.G.O., contributes a valuable article on the municipal service, which presents

an enormous fund of information, not readily accessible elsewhere, on the conditions under which local government officers are recruited and do their work. In a book to which so many authors have contributed some duplication was perhaps unavoidable; the history of public health legislation from 1848 to 1875 is told both by Dr. J. L. Hammond and Sir George Newman and the *Times* joke about Chadwick's acting as a nursemaid to John Bull is quoted in both articles.

Sir George Newman's scholarly article is of special interest to medical readers. He surveys public health problems broadly and in relation to other advances in social amelioration, pointing out that what has been achieved in the last hundred years was based on the work of pioneers in the eighteenth century and even earlier. More might with advantage have been said of the later developments of preventive activity; for there is only the merest mention of the progress made in the last thirty years in maternity and child welfare—probably the best example that could have been given of the co-ordination of municipal and voluntary effort—and in the control of tuberculosis and venereal disease. Any space needed for this purpose could have been secured by curtailing the account of the national health insurance system, which has only a remote connexion with municipal progress.

The book leaves a profound impression on the reader of the range of responsibility now undertaken by the local authorities of this country. Modern advances in science lead to continual additions to their duties, and there is hardly a year in which some

new field of activity does not begin to be explored. It is not surprising that the old local government areas have become unsuited to the new needs, and that drastic readjustments of structure to function are widely regarded as necessary. Those who wish for authoritative guidance on these and other problems of local government—problems that directly affect the daily lives of all of us—cannot do better than study this important book.

No Mean City: A Story of the Glasgow Slums

By ALEXANDER MCARTHUR and H. KINGSLEY LONG. London: Longmans, Green and Co., Ltd. 1935. Pp. 324. 7s. 6d.

THIS book is based on the unpublished novels and notebooks of Mr. McArthur, an unemployed Scottish baker who was born in the poorer part of Glasgow and has lived there all his life. The material has been put into its present form by Mr. Kingsley Long, a London journalist. It covers the period from 1921 to 1930, and the authors believe they have drawn an unexaggerated picture of conditions in the tenements and of life amongst the gangster element of the worst of the slums. If the book is horrible, and it is, that is because the reality of extreme poverty and the a-morality which it engenders is itself horrible. The book may come as a shock to those who dislike plain speaking about the facts of slum life and would prefer to have the evil thing covered up and hidden out of sight, but it is only the realisation of what the slums are which will rouse public opinion to the pitch of getting rid of them; and this book is to be welcomed by all who care for the better housing of the people.

Forensic Chemistry and Scientific Criminal Investigation

Third edition. By A. LUCAS, O.B.E., F.I.C., formerly Director, Chemical Department, Egypt; Fellow of the Chemical Society; Member of the Society of Public Analysts; Member of the Medico-Legal Society. London: Edward Arnold and Co. 1935. Pp. 376. 18s.

It is refreshing after a surfeit of works on the chemistry of blood and urine to meet a book on legal chemistry, a subject of growing importance in the courts (see p. 1013). Mr. Lucas writes for the chemist who is concerned with the investigation of crime. The list of subjects covered in his pages varies from the familiar blood stains to the detection of counterfeit coins and of robbery from letters and parcels, and at first sight one would imagine that chemistry had very little to do with some of the topics mentioned. But the author, clearly a man of very wide practical experience, doubtless has good reasons for including all the material here collected though the minute detail with which certain simple operations are described, notably the mixing of plaster-of-Paris in the chapter dealing with foot-prints, will certainly weary some of his readers.

It is quite clear that, in addition to a knowledge of chemistry, anyone specialising in this kind of work would have to become a detective of no mean ability, and one shudders to think what would happen to innocent and guilty alike if the instructions were followed by a person who was less experienced in methods of detection than in methods of the laboratory. The work will prove valuable to anyone engaged in this special subject, and the more general student of chemistry will find much to interest him in its pages.

Gray's Anatomy

Twenty-sixth edition. Edited by T. B. JOHNSTON, M.B., Ch.B., Professor of Anatomy in University of London, Guy's Hospital Medical School. London: Longmans Green and Co., Ltd. 1935. Pp. 1516. 42s.

THE appearance of the new edition of "Gray" has been awaited with interest, because it was known that it would be written throughout in the new (British) terminology, and that certain changes would be incorporated in it. The volume now to hand is a magnificent achievement—a book which is not only profitable but pleasurable to read. The main changes introduced (after nomenclature) have to do with osteology, which section, it is announced, has been largely rewritten and rearranged in different types so that the value of the section for junior students might be increased and the modern method of teaching supported. It is disturbing to think that a great text-book should be swayed by pure utilitarianism, or should take account of the babblings of the uninformed, so that we turned with a little apprehension to the section concerned. Here we were at once reassured. The work has been done most carefully; if anything, the value of the description has been enhanced by the changes. We would like to see more stress laid on the sexual differences in ossification times, and none placed on the participation of the median cartilage in the growth in depth of the vomer, but beyond these small matters we found nothing which failed to please us. All concerned in the production of this work deserve congratulation.

Chirurgie de la tuberculose pulmonaire

By A. BERNOT, Médecin-directeur du Sanatorium des Fougerays à Châteaubriant; and H. FRECHAUD, Membre correspondant de la Société Nationale de Chirurgie. Paris: G. Doin et Cie. 1935. Pp. 589. Fr.120.

THE divergence of opinion that exists on the indications for and the technique of the various operations for pulmonary and pleural tuberculosis is well exemplified in this latest contribution from France. The ideal method for collapsing the lung by thoracoplasty has not yet been discovered: the search continues for the technique which will give the most efficient collapse with the lowest mortality. In this book the authors quote freely views of many authorities (chiefly French), and discuss all the possible combinations of the different methods of collapse therapy, without, however, having arrived at any clearly defined generalisations. The result is a book of considerable size with such a wealth of information that the reader is left somewhat bewildered, and the seeker for a guiding hand would find it difficult to pick out principles to which the authors hold firmly. The absence of an index does not make things easier. In the section dealing with phrenicectomy, the short paragraphs summarising the authors' ideas about the indications for this operation, based on personal experience of 114 cases, are somewhat at variance with generally accepted views. The balance of the book is curiously uneven; whilst no less than 26 pages are devoted to the anatomy of the posterior scapular artery, the indications for a total thoracoplasty are dismissed in two or three pages. The numerous illustrations are well executed and most informative.

"Why Marry?"

By SYBIL NEVILLE-ROLFE. London: Faber and Faber Ltd. 1935. Pp. 160. 3s. 6d.

THERE is no subject more difficult to regard impartially than sexual morality. The bulk of what is written falls into two general classes, depending upon whether the writer regards marriage as a sacrament or as a social convenience with biological implications. The book under review is a hybrid between these two classes. Its author is the able secretary of the British Social Hygiene Council, an organisation primarily aiming at the suppression of venereal diseases. She professes to approach the problem of marriage in the objective spirit of scientific inquiry; but the reader cannot avoid the impression that Mrs. Neville-Rolfe's attitude is unconsciously coloured by her daily work. The various problems dealt with—pre-marital adventures, divorce, the honeymoon, &c.—are in fact approached, not in the detached spirit of the investigator, but rather in that of the moral propagandist who knows how to select her facts to support her doctrine. The original material contained in the book is mainly composed of extracts from letters which the author has received. Some of these are surprisingly naive. The general thesis of the book is that indulgence in sexual activity outside of marriage is the expression of mental subnormality, abnormality, emotional juvenility, or failure of psychological integration.

British Journal of Surgery

THE October issue (Vol. XXIII., No. -90) contains the following papers:—

Traumatic Hæmangiomatous Tumours of Skeletal Muscle, by ROBERT MALLER (Glasgow). A total of 256 recorded cases are reviewed and a case is reported in which the traumatic origin seemed certain. The lack of capsulation and the progressive enlargement are explained as arising from the repeated traumata of muscular contraction.

Two Cases of Hæmangiomata of Voluntary Muscle, by E. N. MACDERMOTT (Galway). The calf muscles and the erector spinæ were affected. The rarity of correct pre-operative diagnosis and the local malignancy of an otherwise benign tumour are commented upon.

The History of Plaster-of-Paris Technique in the Treatment of Fractures, by J. K. MUNRO (Singapore). The evolution of weight-bearing splints is traced from the stiffened bandages used in the time of Hippocrates. The advantages of early function are discussed.

Hæmorrhage per Rectum as an Indication of Disease in Meckel's Diverticulum, by JUDSON T. CHESTERMAN (Sheffield). The typical syndrome is sudden rectal hæmorrhage in a patient 5-15 years of age, the cause being unexplained by sigmoidoscopy or blood examination. Abdominal colic may precede or accompany the bleeding. Four cases are described.

Intussusception of Jejunum into Stomach through a Gastro-enterostomy Stoma, by J. A. MUNRO CLARSON and W. DOUGLAS MACFARLANE (Glasgow). The accident occurred six years after operation as an acute surgical crisis, and proved fatal within 24 hours.

A Further Note on the Development of Cysts in Connection with the Semilunar Cartilages of the Knee-joint, by ROBERT OLLERENSHAW (Manchester). The experience gained by operation on a further 20 cases is summarised. One case is reported of a cyst projecting towards the centre of the joint.

Angioma of the Kidney: Report of a Case, with an analysis of 26 previously reported cases, by R. H. JOCELYN SWAN and HAROLD BALME (London). Symptomless hæmaturia is the main feature. Nephrectomy is the treatment advised in most cases.

Thrombosis following Strain, by R. H. O. B. ROBINSON (London). Two cases are reported, in both of which the thoraco-epigastric artery appeared as a thickened and tender cord, as a result of thrombosis.

The Late Results of Operations on the Biliary Tract in 359 Cases, with Cholecystographic Studies in 18, by JAMES H. SAINT (Newcastle). The operations were performed between 1907 and 1922. Cholecystectomy gave a greater proportion of good results than did cholecystostomy; and drainage of the common duct was particularly successful. Cancer of the gall-bladder was not an ultimate cause of death in any case.

Traumatic Rupture of the Congenital Solitary Kidney, by J. R. H. TURTON and J. C. F. LLOYD WILLIAMSON (Brighton). A case is described. The means is discussed of obviating nephrectomy in such cases.

Squamous-cell Carcinoma of the Renal Pelvis: Report of a Case, by MAURICE SILVERSTONE (Birkenhead). Two types are recognised: one soon involving the kidney substance, the other producing hydronephrosis.

Sacro-coccygeal Cysts and Tumours, by R. W. RAVEN (London). Teratomata are regarded as malformations. The origin of dermoids, of cysts of the post-anal gut, and of cysts of meningeal origin is described and illustrated.

Pylephlebitis complicating Appendicitis and its Treatment by Ligation of the Mesenteric Veins, by A. M. STEWART-WALLACE (London). Case with recovery. The diagnostic importance of post-operative rigors is emphasised.

Intestinal Obstruction by Gall-stones, by C. P. G. WAKELEY and F. W. WILLWAY (London). The history is reported of 11 cases, all treated by operation. The practical importance of double obstruction is pointed out.

Lymphatic Spread in Cancer of the Rectum, by W. B. GABRIEL, CUTHBERT DUKES, and H. J. R. BUSSEY (London). A hundred operation specimens have been examined and the findings are discussed. Metastases were discovered in 62 per cent., confined, in half the cases, to three glands or fewer.

The Role of Sympathectomy in the Treatment of Peripheral Vascular Disease, by R. I. HARRIS (Toronto). Results obtained in the last four years by operation on 24 cases.

The Peripheral Nervous System, by H. H. WOOLLARD (London). A practical account of the distribution to the limbs and viscera of the various components of the sympathetic and pelvic nerves. Appended is a brief résumé of Dale's findings on the intermediate function of acetylcholine and adrenaline.

The Results of Sympathectomy: An Analysis of the Cases Reported by Fellows of the Association of Surgeons, by J. PATERSON ROSS. The value of the operation is examined in disorders of the circulation, in Hirschsprung's disease, in intestinal stasis, and in renal pain and causalgia. The possibility of consequent disabilities is assessed.

Central Control of the Sympathetic Nervous System, by JOHN BEATTIE (London). An account of the functional significance of the sympathetic and central connexions of the hypothalamus as revealed by recent experimental work.

The Technique of Sympathectomy, by E. D. TELFORD (Manchester). Attention is drawn to the importance of the essential automatism of plain muscle, as partly explaining the tendency to gradual deterioration of immediate good results; and to the variations in the anatomy of the autonomic nervous system. Causes of failure are related to possible errors in technique.

The Effects of Obstruction of the Urinary Tract, and the Effect of Experimental Interference with the Blood-supply of the Kidneys, with particular reference to the Formation of Stones. Two papers by J. GRAY from the Henry Lester Institute, Shanghai. The results obtained in rabbits show that the factors favouring the formation of stones are damage to the epithelium of the pelvis, either by partial obstruction or by vascular interference insufficient to damage the kidney seriously; a dietetic imbalance in the proportion of calcium and phosphorus; and excess of vitamin D in the diet. The stones form around a nucleus of epithelial debris in the cavity of the pelvis, in the presence of an increase of the calcium content of the kidney.

MEMOIRS OF A CAMP FOLLOWER. By PHILIP GOSSE.—This book, which was given favourable notice in THE LANCET (1934, i., 585) on its first appearance, has now been issued by Messrs. Longmans Green and Co., Ltd., London, at 5s.

THE LANCET

LONDON: SATURDAY, NOVEMBER 2, 1935

THE INDEPENDENT MIDWIFE

ABOUT two years ago a council was formed under the chairmanship of Dr. WATTS EDEN to look into the efficiency of the midwifery service in this country and to consider how it is affected by the ability of midwives to earn a livelihood. This joint council was representative in high degree of the professional bodies competent to judge about the problems of childbirth and their solution; it was asked to prepare a detailed scheme for the enlistment of midwives in an organised service, suited to the needs of each district, and leaving the parturient woman free to choose her own attendant; and its report when it was presented last February carried much weight. The council was unanimous in its findings that domiciliary midwifery should continue to form the basis of the maternity service, that a certified midwife should be present at every childbirth, and that the status and remuneration of midwives must be improved. But it went further than this and, with practical unanimity, recommended the establishment of a salaried service of midwives, with the same status as health visitors, under the control of the appropriate local authority. Such a scheme might absorb about 4500 midwives who had not previously been so employed. Obviously it could not include all midwives now in practice, let alone those on the inflated register of the Central Midwives Board, and the council recognised that there must be compensation of those not absorbed in the scheme for the loss of their practice. Six months later the London County Council approved the proposal to establish a salaried service, but Mr. SOMERVILLE HASTINGS, on behalf of the hospitals committee, stated that he was unable to accept the principle of compensation from the rates. It was estimated that 158 midwives would be required by the L.C.C. and several times this number at present notify their intention of doing some midwifery in the county. There has been some talk of a draft Bill for the establishment of a national midwifery service, and proposals have been submitted to representatives of local authorities for their comment.

The crux of the problem is the question of compensation, for it is hardly likely that any scheme of salaried service will prove acceptable to organised midwives which does not include some provision for those who wish to serve and are not accepted, if not for those who are unfitted by age or infirmity. The Joint Council suggested in its report that compensation on these lines might cost no more than £200,000, but admitted that any figure could only be provisional until it was ascertained how many independent midwives are now practising. To obtain this and other information at first hand the Midwives' Institute undertook to send out a questionnaire not strictly limited to

its members. The questionnaire was a searching one, asking not only for the number of cases attended in two specified years (1929 and 1934) and the fee asked, but for details of the economic background of the midwife's life. Some 8000 forms were sent out and more than half these have been returned, not only filled in but often containing corroborative information. Lady FORBER, who will still be better known to many of our readers as Dr. JANET LANE-CLAYPON, offered to analyse the replies for the Institute, and she has embodied the result of her analysis in the Fynes-Clinton lecture delivered at the Institute on Thursday of last week. Lady FORBER found herself unable to examine the whole material in time for this lecture, and she therefore confined her study to three counties, Yorkshire, Durham, and Hampshire, and a part of Lancashire. The analysis relates strictly to independent midwives, excluding those who run nursing-homes without district practice, and maternity nurses who only register as a safeguard. At least one-half of all the independent midwives in the areas considered replied to the questions and the information obtained from them is sufficiently surprising. It will, for instance, be news to most people that the total number of married midwives is greatly in excess of either widowed or single; rather over 10 per cent. of midwives in the sample analysed are over 60 years of age, and many of them have larger practices than the younger women. Few enter practice under the age of 30, and most of these are young married women. The older women have mostly been in practice for a great part of their lives and continue to work as long as they can. Equally unexpected is the fact that in the interval between 1929 and 1934 there has been an increase (Hampshire excepted) in the number of cases attended by independent midwives; but the increase in the number of midwives practising is larger still, so that there is a fall in the average number of cases taken. Of the 562 midwives in independent practice in the areas studied who made returns, half took less than 50 cases in the year, only one out of five had over 100 cases. Fees vary in different areas; in some the charge for any confinement is 42s., in others 35s. for a primipara and 30s. for a multipara. Lady FORBER concludes that a third of all independent midwives cannot be earning more than £50 a year, and probably considerably less, while only one in seven earns £200 or more. Few obtain their whole fees; a midwife tends to be the last to be paid. Except for a small minority the practice of the independent midwife does not afford a living wage, and the reasonable livelihood of the minority is obtained only by attendance on an unreasonable number of cases.

That is the position, and, as Lady FORBER remarked, the facts need to be faced, for the independence of the midwife can hardly be said to exist if she is unable to secure a livelihood as a midwife. Many factors contribute to the difficulty of the position. There are clearly too many women training as midwives with little or no intention to earn their livelihood as such.

Those who take the diploma of the Central Midwives Board as the final touch of a nurse's training or as a branch of social service are entitled to attend confinements if they register with the local supervising authority and to compete with the professional midwife. Surely, said Lady FORBER, a more specialised training should be required for those who profess midwifery than those who take the S.C.M. qualification as a side-show. Something might be done to increase the number of cases available for midwives. It is the policy of the Joint Council that a midwife should be available at every childbirth, having behind her a doctor who has seen the patient beforehand and is ready to come if required. This proposal would finally eliminate the handy woman. In a few places she seems already to have disappeared but in others the many complaints in the schedules testify to her continued activities. Midwives also complain of the loss of practice owing to women who do not actually require in-patient care being attracted to hospital by the low fees charged. At some of these hospitals money is being expended by the taxpayer for the training of midwives in a profession already overloaded and at the expense of its practising members. Apparently, too, midwives seldom get paid for miscarriages or abortions, and as Lady FORBER remarks, all abortions are abnormalities. They frequently give rise to trouble at the time and some midwives report that the only maternal deaths in their practice have followed a recent abortion or a previous pregnancy which ended before term. The problem of the domiciliary midwifery service is indeed complex. The independent midwife, while recognised by Statute, is squeezed from all sides; work has been added for which she receives no extra pay, while the maternity benefit which is obtained on her signature is often used for other purposes; she often fails to get a reasonable fee for attendance on necessitous mothers. These are all matters which claim immediate attention, for even if a salaried service is coming it must take time before it gets into working order, and it can hardly be securely based except on the experience of a fair and free midwifery practice.

ELECTRIC SHOCK

THE first recorded death from electricity was that of a stage carpenter, who in 1879 touched the switch of a dynamo in a Lyons theatre. Since then the use of electricity for industrial and domestic purposes has increased rapidly, and there have been rises in the death- and accident-rates; though fortunately, as Dr. CRITCHLEY told the Medical Society last Monday, conditions in this country have been made relatively much safer. The prevention of electrical accidents comes within the province of the electrical engineer, but to the medical profession the study of the effects of electricity on the human body is one which presents many complex and contradictory features. It is impossible, in the present state of our knowledge, to predict with certainty what will happen when a man receives an electric shock of, say, 250 volts A.C. One man will die,

but another will be none the worse for the experience. Death has been known to be caused by a current of 65 volts A.C., but again a man has received a shock of 48,000 volts A.C. with little or no effect. It is known also that, at medium voltages, alternating currents are more dangerous than direct currents, especially if they pass through the thorax. At very high voltages, however, direct currents seem to be more dangerous than the alternating variety. The explanation of these apparently contradictory facts lies in a combination of electrical and physiological factors, so that in any satisfactory investigation of the features of electric shock, coöperation between electrical and medical experts is desirable. We publish on p. 1021 a contribution by Captain C. W. HUME on electric stimulation in relation to subjective phenomena in electric shock. He comes to the conclusion that an electric shock which does not immediately produce unconsciousness is capable of causing severe pain with temporary paresis of the speech mechanism. The fact that the victim may be apparently unconscious, yet retain perception, makes him dissatisfied with the widespread use of electricity as a means of stunning animals before their slaughter, and also as an anæsthetic for veterinary operations.

JEX-BLAKE in 1913 drew attention to the differences in susceptibility to electric current shown by animals of the same and different species. In man susceptibility varies not only from person to person but also in the same person from moment to moment, owing to the changing conductivity of the human organism. JEX-BLAKE thought that death from electric shock in man is almost always due to a non-reversible ventricular fibrillation, but with very high voltages death might be caused by asphyxia following paralysis of the respiratory centre. HILARY LONG¹ in a review of recent observations on the subject comes to the conclusion that death is rarely due to ventricular fibrillation. The work of LANG-WORTHY, PANZE, and JELLINEK has shown that the main effect of electric shock is on the central nervous system, particularly the respiratory centre. The post-mortem changes are usually those of asphyxia, though lesions in the nervous system are sometimes found, especially when death has been caused by the higher voltages. It is important to understand the cause of death in such accidents, for otherwise it is hard to say what treatment should be adopted in cases not immediately fatal. The Viennese school, of which JELLINEK is the leader, maintains that death from electric shock is due sometimes to a combined cerebral and pulmonary congestion, occasionally to asphyxia, and very rarely to a sudden stoppage of the heart. MELISSINOS,² of Athens, who like LONG has studied the subject with JELLINEK, states that the treatment consists in artificial respiration and lumbar puncture. He recalls that JELLINEK has reported cases in which artificial respiration had no effect until lumbar puncture was done to release the

¹ Long, M. H. E.: *Med. Press and Circular*, August 21st, 1935, p. 150, and August 28th, p. 172.

² Melissinos: *Echo méd. du Nord.*, Sept. 15th, 1935, p. 459.

pressure on the central nervous system and chiefly on the respiratory centre. He suggests that the cerebral and pulmonary congestion found in electric shock is secondary to the direct action of the current on the vasomotor system. It is known that electric currents in the body travel mainly along the blood-vessels. KOUWENHOVEN, HOOKER, and LANGWORTHY³ have shown experimentally that it also passes through the cerebro-spinal fluid, which has a lower resistance than blood. The statement by JEX-BLAKE that a heart in ventricular fibrillation following electric shock cannot revert to normal rhythm has since been questioned; indeed, LONG describes an experiment in which JELLINEK showed that ventricular fibrillation induced by an electric current is a reversible process. He gave a monkey a shock of 110 volts A.C., one electrode being placed on the right side of the chest and the other on the left high. Immediately after the passage of the current an electrocardiogram showed that the heart had gone into ventricular fibrillation. The condition persisted for 19½ seconds after which the heart spontaneously reverted to its normal rhythm. LANGWORTHY has found that the hearts of rats likewise recover their normal rhythm spontaneously after being thrown into ventricular fibrillation by electric currents. Recently JOSEPHthal⁴ has recorded a case of post-diphtheritic ventricular fibrillation with recovery, and SCHWARTZ⁵ a case in which a patient had a number of attacks of unconsciousness associated with transient ventricular fibrillation. It seems therefore that ventricular fibrillation is not necessarily non-reversible or fatal.

Emotional or psychic factors, as HILARY LONG points out, might explain to some extent the variation of responses obtained in electric shock. A man's tolerance of electric currents will depend partly on external factors such as the presence of moisture, and also on his mental state at the time of the accident. If he is exhausted or emotionally disturbed the effect of the electric current will be more severe. Again, if a man is expecting an electric shock, it will not affect him as much as if it came as a complete surprise—a fact which may explain why many electricians seem to develop an immunity against electric currents of medium strength.

SURGERY OF THE SYMPATHETIC

DURING the past ten years so much thought has been devoted to the surgery of the sympathetic nervous system that it is surprising to find little agreement about the precise indications for operation and about the significance of many details in surgical technique. The conceptions of the physiology of the autonomic system upon which surgery has been based have altered considerably during this period, and those who have attempted to study its functions by observing the effects of sympathectomy in man have been much handi-

capped by the presence of permanent structural changes in the denervated organs which interfere with their normal activity. Those who planned the operations were influenced by the ideas, gleaned from animal experiment, that sympathetic impulses were exactly antagonised by those of the parasympathetic nerves, and that the process of regeneration after excision of a portion of a sympathetic trunk was so active that a considerable gap could be bridged by the proliferating nerve-fibres. It is now realised that the interpretation of such experiments may be confused by the combination of sympathetic and parasympathetic fibres in the same nerve trunk; and, further, that the motor or inhibitory function of certain nerves cannot be deduced merely from their anatomical source and their morphological characters. The researches of DALE and his co-workers have shown that many of the cerebro-spinal and all the autonomic nerves produce their effects through the intermediation of chemical substances, and it must be noted that though adrenaline is formed at most of the sympathetic nerve-endings, acetylcholine, which mediates all the parasympathetic impulses, is the substance produced at the sympathetic endings in sweat-glands and at some of those in the gut. The time has therefore come to review our surgical experience in the light of these researches, and with the knowledge that regeneration of sympathetic fibres after excision is now believed to be a negligible factor.

This attitude is reflected in a series of articles in the current number of the *British Journal of Surgery*, reviewed on p. 1008. The conservatism of British surgeons is shown by the fact that in this country sympathectomy is confined almost exclusively to lumbar and cervicothoracic ganglionectomy, presacral neurectomy, and perivascular operations on the mesenteric and renal arteries. The indications also are limited to peripheral vascular disease, intestinal stasis, and the relief of visceral pain, and little or nothing is heard of sympathectomy for epilepsy, neuralgia, retinitis pigmentosa, spastic paralysis, asthma, tachycardia, and hypertension. Surgeons are learning to rely more and more upon preoperative tests in selecting the cases suitable for operation, and reluctance to embark upon the treatment of these conditions may be attributed partly to the difficulty or impossibility of applying such tests to them, and partly to the unconvincing nature of reports from clinics abroad. The value of the preliminary estimation of the degree of vaso-spasm which may accompany any form of peripheral vascular disease is demonstrated by R. I. HARRIS of Toronto, whose figures show how closely the rise of temperature following temporary block of the sympathetic nerves with novocain is related to the improvement in the circulation after sympathectomy, though he is careful to point out that the result of permanent denervation is often more gratifying than the anæsthetic test might lead one to expect.

Turning to the consideration of surgical technique, it is remarkable that surgeons are still undecided upon the extent of the excision necessary to denervate a given organ. In the case of the

⁴ Josephthal, F.: *Wien. Arch. f. inn. Med.*, Dec. 10th, 1934, p. 15.

⁵ Schwartz, S. P.: *Arch. Internal Med.*, February, 1932, p. 282.

oesophagus and the colon this is due to the incompleteness of our knowledge of their nerve-supply; but in the case of the limbs it is attributable to the conflicting evidence of physiological experiment and surgical experience regarding the relative values of preganglionic and postganglionic sections. WHITE'S experiments¹ seem to show that removal of the ganglion cells renders the denervated vessels over-sensitive to the action of circulating adrenaline, and some clinicians have seized upon these observations to explain why the results of lumbar ganglionectomy, which is a preganglionic section for the foot, are on the whole so much better than those of cervicothoracic ganglionectomy, which is of course postganglionic for the hand. TELFORD suggests dividing the thoracic trunk below the third ganglion in order to achieve preganglionic section of the arm supply, and points out that this operation has the added advantage of avoiding the unwanted Horner's syndrome, which is inevitable after excision of the stellate ganglion. The late results of this operation will be awaited with much interest.

In attempting to explain the recurrence of symptoms after sympathectomy regeneration of nerve tissue after a properly conducted operation may be left out of account, and it is probable that the secret lies in the automatic activity which the

organs innervated by the sympathetic all seem to possess. The loss of sympathetic control may sometimes render them more susceptible to stimulation by adrenaline, but there is another factor which must not be forgotten. The analysis of the results of sympathectomy prepared for the Association of Surgeons by PATERSON ROSS shows that the success of these operations largely depends on the severity of the disease for which the operation has been performed. This is especially noticeable in Raynaud's disease, in thromboangiitis obliterans, and in the cold blue legs of poliomyelitis and erythrocyanosis, and it may be generally accepted that sympathectomy is of greatest value in the early stages of disease, when denervation may help to rectify a disorder in the function of an organ which has not yet suffered any considerable alteration in its structure. Recurrence of symptoms after operation is not infrequently due to such structural changes, signs of which again manifest themselves after the earliest paralytic phenomena of denervation have passed off. Judgment should not be passed upon the value of sympathectomy without giving careful consideration to the nature of the disease for which it is practised. There is no doubt that the results are often disappointing, but this is the fault not of the operation but of the surgeon who has failed to take sufficient care in selecting the cases suitable for sympathectomy.

ANNOTATIONS

THE RIGHT TO DIE

EARLY in December a meeting is to be held at the house of the Royal Society of Medicine to inaugurate a public society, to be known as The Voluntary Euthanasia (Easy Death) Legalisation Society, which has been formed under the presidency of Lord Moynihan with Mr. C. J. Bond as chairman of the executive committee and Dr. Killick Millard as hon. secretary. The society owes its origin to Dr. Millard, who three years ago devoted to this subject the whole of his presidential address to the Society of Medical Officers of Health, submitting for their consideration the draft of a Parliamentary Bill to legalise the painless killing, at their own wish, of persons suffering from incurable, fatal, and painful disease. This draft Bill has since been revised by high legal authority without substantial modification and is now ready to be introduced by Lord Moynihan in the House of Lords at some suitable time. To meet possible objections on religious grounds, a statement that voluntary euthanasia as proposed by this society is not contrary to the principles of Christianity has been drawn up and signed by a number of representative anglican and nonconformist ministers. The proposal too is regarded as gaining support from what Sir (Saint) Thomas More wrote in "Utopia" about euthanasia, although he did not actually use the word. Copies of the draft Bill, price 6d., can be obtained from Dr. Millard at The Gilroes, Leicester.

WHITE BILE

THE discovery of colourless contents in the gall-bladder or bile-ducts is unusual, and the surgeon may find it hard to assess its significance. Where the gall-bladder is completely isolated the assumption

will be that its wall has absorbed the bile-pigments, and examination of the contents will show that the bile salts, too, have been absorbed. The fluid may be clear or turbid, and the condition may be the outcome of obstruction of the cystic duct either by tumour or by calculus. That a somewhat similar condition may arise in the isolated bile-ducts was demonstrated by a case reported last year by Mr. Norman Lake.¹ This was one in which the lower ends of the common bile-duct and of the cystic duct were simultaneously blocked by new growth, and the result was enormous distension of the bile-ducts, to the calibre of the jejunum, their content being as colourless as cerebro-spinal fluid. E. Melchior² now points out that there is a distinction between the case in which the liver and ducts are still excreting bile of normal colour—which is later decolorised—and that in which there is a failure, primary or secondary, of the liver cells. Quite often this failure is due to back pressure through blockage of the ducts, and drainage of the biliary system may restore the normal liver function and relieve the associated jaundice. In other cases the hepatic failure appears to be primary, without biliary obstruction. Melchior thinks, however, that there is no essential difference between the two classes of case, once the damage to the liver cells has gone far enough. Most probably, he believes, infection plays a considerable part in the causation, although he cites cases in which bacteria could not be found. His advice is that when there is biliary obstruction and the common bile-duct is found to be distended with clear colourless, or milky fluid, the prognosis should be guarded, especially if the obstruction is suspected to be of

¹ THE LANCET, 1934, II, 753.

² Presse méd., August 21st, 1935, p. 1316.

long duration. After operation the reappearance of pigment in the bile draining through the tube is of course a good sign, but final failure of the liver occurred in some of his cases, with reappearance of colourless "bile." Sometimes the flow of fluid was excessive, a condition which Melchior terms "hypercholorrhée" being established. Two litres or more of colourless fluid might drain in the day, and the patient suffer accordingly from the symptoms of rapid fluid loss, sometimes with widespread hæmorrhages (visceral and subcutaneous) in addition. The liver is apt to be tense, enlarged, and firm, and its surface is spotted with tiny white channels looking somewhat like abscesses. These are the small hepatic ducts distended with the same white fluid that appears in the main ducts.

THE FORENSIC CHEMIST

MINDFUL of the debt which legal medicine owes to chemistry, the Medico-Legal Society have elected Mr. C. A. Mitchell, D.Sc., to be their president. In the address delivered to them on Oct. 24th he was able to show how wide had been the application of chemistry in the courts during the last fifty years. In the trial of Palmer, the Rugeley murderer, in 1856 the chemical evidence of strychnine in the body of Cook was discredited by the medical evidence adduced for the defence. Nowadays the chemical evidence is often more decisive than the clinical findings, and many branches of evidence are now exclusively within the province of the chemist. In questions concerning the adulteration of food and drugs the public analyst has won an independent and highly-specialised position, and there are now more non-medical than medical toxicologists available to assist the police. Only the chemist has been able to explode such medical fallacies as the belief that a drunkard may die from spontaneous combustion, or that a body buried in quicklime is destroyed. Chemical evidence, by showing that fire could start by the accidental mixing of such common drugs as permanganate and glycerin, induced the Court of Appeal to hold that the fires in Kingstown at the time of the Jamaica earthquake in 1907 started as the result of the earthquake and not before it. The chemist is often called upon to identify the wood from which charcoal is made by examining its microscopical structure; to decipher writing on burnt paper; or to decide whether material is damaged by salt or by fresh water. By identifying the dust on the clothes of an Egyptian suspect with the fire-proof lining of a broken safe, a chemist of Cairo brought a burglar to justice, and a coiner was convicted on the evidence of a single particle of alloy found on his file and identical with the metal in counterfeit coins which he was charged with making. The chemist can often pronounce on the genuineness or otherwise of a document, for if a document bearing a date earlier than 1861 is printed on esparto paper it is spurious, as is a document purporting to be printed on wood-pulp paper before 1874. The age of ink in writing can be ascertained with precision by testing the surrounding paper and estimating the extent to which the soluble salts of sulphur and chlorine have permeated it. For periods over two years the chemist uses the older method of studying the formation of the resinous deposit, and the difference in age between two sets of writing on the same paper can be distinguished if one is less than ten or twelve years old. Dr. Mitchell, in these and other examples, brought forward ample evidence why the forensic chemist should be recognised as an

independent ally of the medico-legal expert and why, although he is neither a doctor nor a lawyer, he is certainly not a layman in the medico-legal world.

CARCINOMA TELANGIECTATICUM

THE clinical appearances and prognosis of cutaneous cancer are affected not only by the type of the growth, but also by the nature and plane of the cellular tissues it is invading. A spread in the lymphatic vessels, for instance, with a consequent block in lymphatic drainage will lead to exudation and local œdema of the peculiar solid type which the French have termed cancer en cuirasse, or peau d'orange. Of equal importance and interest, though less often observed, is the result of selective invasion of the cutaneous capillaries and smaller blood-vessels. Such a case, illustrated in natural colour, has lately been reported by Dr. F. Parkes Weber.¹ It concerns a woman of 48 who was operated on for carcinoma mammae in October, 1932, and died from secondary deposits in the pleura and elsewhere in May, 1934. The illustration brings out the localisation of the skin changes in the left flank, but hardly suggests the telangiectatic changes, due, as histological examination eventually proved, to vascular involvement by carcinomatous cells. It appears that the small telangiectases are characteristic of this form of malignant invasion, and if this is so there is every reason to support Dr. Parkes Weber's argument that the name suggested by him, carcinoma telangiectaticum, should supersede that devised for similar cases by H. Küttner, of Breslau, and C. Rasch, of Copenhagen—viz., erysipelas carcinomatosum, or erysipelatoid carcinoma.

FREE FALLS IN SPACE

It was formerly assumed that a free fall of over 100 feet produced unconsciousness or even death; but the use of the parachute, and "delayed parachute jumps" in particular, have disposed of this idea. Delay in pulling the ripcord of a parachute may be thought necessary for either of two reasons: first to avoid entanglement with the aeroplane or collision with other jumpers, and secondly in descents from extremely high altitudes. Captain H. G. Armstrong, of the United States Medical Corps, points out² that a jump from 30,000 feet involves the loss of the jumper's oxygen supply, and that if he opens his parachute at once he may lose consciousness or die before he gets to a level at which he will recover. He uses this as an argument in favour of a rapid "free fall" for the first few thousand feet. But while we may agree that a pilot opening his parachute at 30,000 feet, without using oxygen, would probably become partly or wholly unconscious during the first few minutes of the fall, it is generally believed in this country that in such circumstances a fit man would later recover consciousness, probably before reaching the ground. On the other hand, Armstrong's contention that in a free fall to about 20,000 feet a parachutist would retain enough consciousness to open his parachute is borne out by experiment here, provided no great effort has been entailed in getting clear of the aircraft. His suggestion that if it should be necessary to jump from an aeroplane travelling at a velocity of the order of 360 miles an hour the pilot should not open his parachute till he has lost almost all horizontal velocity is sound

¹ Internat. Clin., 1935, vol. iii., p. 145.
² Jour. Amer. Med. Assoc., Oct. 5th, 1935, p. 1107.

enough in theory; but the practical difficulties in the way of making such a jump are considerable, especially as the circumstances which would make it necessary would sometimes make it almost impossible to climb out of the aircraft without serious injury. In such a case, if he still retained enough control of his machine, he might do better to reduce the horizontal component of his speed by a vertical zoom, which would at least reduce the risk of breaking his neck on attempting to climb out. Once his speed had been reduced to that of his terminal velocity for a free fall at the height at which he is flying (about 190 miles an hour at 30,000 feet) the risk of opening the parachute would be much the same at whatever height he opened it; since the reduction in air density at such a height, which raises his terminal velocity from 119 miles an hour at ground level to about 190 miles an hour, would cause the pull of the parachute to be proportionately less than it would be near the ground, these two changes cancelling one another.

Captain Armstrong has himself made a parachute descent from 2200 feet, and describes his sensations before pulling the ripcord. He felt free from fear and excitement as soon as the machine was cleared; he had some loss of auditory perception but consciousness was unclouded. The only recognisable motion during the first two seconds was slow rotation of the body; during the third and fourth second, with the eyes still closed, even this rotation ceased and the only feeling was that of being suspended in mid air; not until the eyes were opened was a definite sensation of falling experienced. His physical sensations were almost nil. There was no nausea nor vertigo; breathing was regular and unhurried; no abnormalities were noted in the cardiovascular system; the eyes though unprotected were not irritated and vision was normal. The only physical sensation consisted of a very gentle evenly distributed generalised superficial pressure on the downward surface of the body. These experiences in general accord with those described by parachutists like the late John Trantum, who in May, 1933, made the world's record delayed parachute jump from a height of 21,000 feet. On this occasion Trantum used a small supply of oxygen and had previously undergone a chamber test in which the rate of pressure change in such a fall was exactly reproduced, in order to see whether he could sufficiently equalise the pressure on both sides of his tympanic membrane to avoid serious trouble, which he found he was able to do without difficulty. Trantum mentioned the same sensation of tumbling head over heels for about a mile and then gently floating, with his head downwards and the body at an angle of about 45°, and slowly rotating about his longitudinal axis; he said he could control this rotation by merely moving one hand out from his body to act as an air-brake. He too had no sensation of posture without the aid of vision; this is only to be expected, for in a free fall, where the acceleration due to gravity is affecting the whole body except for the retardation due to friction, the fluid in the semicircular canals, without losing any of its mass, loses nearly all its weight and so gives no indication of posture; and since no part of the body is resting on any material thing there is no information to be gained by muscle sense. The loss of auditory acuity may be either local, through the altered pressure on the tympanic membrane, or central; or it may perhaps have been the ordinary deafness which many people experience when exposed to the noise of an aircraft engine.

Armstrong estimates that without the use of oxygen anoxemia begins to develop in human beings at about 10,000 feet, producing dyspnoea at 15,000 feet, unconsciousness at about 22,000, and death at about 27,000 feet. Naturally this can be no more than a rough estimate, since the condition is continuously progressive in relation to both height and time. But we doubt whether dyspnoea occurs in fit pilots at 15,000 feet unless they do an unusual amount of muscular work.

PATHOGENIC ACTINOMYCETES

IN the past the actinomyces group has been in a sad way, falling, as it were, between two stools. This group of infective micro-organisms lies on the borderline between the true fungi and the bacteria which multiply by fission. It does not yield easily to orthodox bacteriological methods, and has been neglected by mycologists. Consequently the descriptions of strains that have been isolated are often poor and ambiguous, and the resulting confusion has inspired ambitious rearrangements and renamings of the group which have led to still greater confusion. Recently the need for a reliable system of classification has been aggravated by the description of actinomyces isolated from conditions other than frank mycetomata. The pathogenicity of strains from the latter, though still presumptive, is fairly well established. There are a number of strains, however, whose connexion with the lesion in which they are found is less demonstrable. Among such strains are those isolated by Dr. A. G. Gibson¹ from the enlarged spleens of sufferers from splenic anaemia, Banti's disease, and acholuric jaundice. A few years ago Dr. Gibson sought assistance from the Medical Research Council in a systematic examination of these strains, and at the same time presented to the National Collection of Type Cultures, maintained by the Council at the Lister Institute, a fully documented series of the organisms. These strains formed the nucleus of the material studied, in parallel with another and much larger series from other sources, by Miss Dagny Erikson,² who has now published a report on her systematic investigations. In all 50 strains were examined by her, and on the basis of the type of growth-mass have been divided into two main groups and further subdivided according to pigment production, proteolytic powers, and their growth in and on a variety of culture media. By these means Miss Erikson has regrouped several known strains and created 15 new species. She fails to confirm the extreme degree of variability claimed for the group by some observers, and finds that though individual characteristics vary with the culture medium used, there is a sufficiently stable aggregation of them to enable a species to be recognised as such. Full descriptions of the colonial and individual morphology of 25 strains are supplied, illustrated by over 100 line drawings. The value of this careful study would have been enhanced had the sizes of the organisms been explicitly stated and had terms like "large," "small," "minute," and "pin-point" applied to colony form been translated into measurements either of modal size or of limits of variability. In all other respects Miss Erikson's report provides a most useful groundwork for future workers, both as a reference to type species and a basis of classification. More differential methods

¹ The Mycoses, 4th Edition, London, 1920.
² The Pathogenic Group, Medical Research Council, H.M. Stationery Office. Pp. 61. 1s.
 nomyces No. 203.

will no doubt be required. Biochemical tests have a limited use, owing to the slowness of growth and the poor fermentative power of the organisms, and advance may most reasonably be expected from the application of the methods developed by J. Tomesik,³ Stone and Garrod,⁴ and J. T. Duncan⁵ in their serological analyses of some of the lower fungi.

"NARCO-LOCAL" ANALGESIA

THE advantages which can be gained by the use of local instead of general anaesthetics for major surgical operations have more often been pointed out by continental surgeons than by those of English-speaking nations. An article, however, in the *Medical Journal of Australia* of July 6th, in which Mr. C. E. Corlette recounts his views and practice after an experience of 18 years, gives impressive support to those who recommend local analgesic methods. Corlette points out clearly the disadvantages of purely local means of obviating pain and the necessity for dealing effectively with the psychological aspect of operation and of protecting the patient both from mental anguish and from all memory of any actual pain if this is inadvertently inflicted. The essential feature of his method, apart from gentleness in operating, is the logical and reasoned employment of suitable premedication. This is carried out by divided doses, generally two, of morphia and scopolamine. The first injection is two hours before operation; most surgeons who use this premedication have erred in giving it at too short an interval beforehand. Moreover the susceptibility at different ages has been insufficiently studied. Corlette finds that a man of 20-25 years of age is between two and three times as tolerant of morphia and hyoscine as he is thirty years later. The dosage is arranged accordingly, and the article provides a table showing the routine doses from 11 to 84 years of age. In practice, of course, these figures are not rigidly followed, the experienced man taking into account the physical and mental features of the patient which he knows influence susceptibility in one direction or the other. It is certain that if a surgeon can acquire the experience and will take the necessary trouble he can achieve by "narco-local" analgesia results which it is impossible to better, if to equal, when general anaesthetics have to be relied upon.

ANONYMOUS LETTERS

LAWYERS have more direct concern with the writers of anonymous letters than have psychiatrists, but the latter can properly claim such people as subjects for their art. A few reports on the psychological aspect of this disagreeable symptom are available. In the latest of them however Dr. Karl Gross⁶ shows himself cautious as to its morbid significance; he points out that not all of those who write anonymously are criminals or scoundrels or psychopaths; they may be journalists or politicians. Apart from such obvious exceptions, questionable only by the cynic, the majority of those who write anonymously do so to gratify or manifest inclinations which are part and parcel of a psychopathic disposition. Few of them do so on the grand scale of a Junius; their field is often petty, and the style appropriate to the matter; but whatever the abilities or aim of the writer, his motive is constantly to be found in thwarted desires and morbid tendencies.

This does not mean that he is independent of his present milieu and driven solely by forces within himself. The violent suppression of opinion which now obtains in many countries is a manure in which these particular weeds sprout amazingly. Among the outstanding characteristics of the anonymous letter writer on which Dr. Gross remarks are obscenity and sexual attacks; the usual decencies are cast aside. Few of the writers are insane; many of them are hysterical and given to fantastic lying; others are hypomanic, compulsive, or paranoid. They may be of any age; the majority are women, and they are more prone than men to be salacious in such letters. They may persist for many years in their attentions, which are often prompted by jealousy, envy, or revenge. A craving for thrills and artistic display may be evident, and occasionally other members of the family have been induced to join in the business. The treatment of the psychopaths here in question is usually in the hands of the courts; but it would be a good thing if, in deciding it, not only the noxiousness of these people to society could be taken into account, but also the degree of their accessibility to the methods of modifying morbid trends now at the disposal of the psychiatrist.

BERI-BERI OR TREMATODE INFECTION?

THAT cysticercus infection of the brain may mimic epilepsy has been clearly shown by Major-Gen. W. P. MacArthur. A parallel discovery, made in the Philippine Islands,¹ is that the symptoms of wet or cardiac beri-beri are sometimes traceable to infection with minute trematodes of the family heterophyidae. These parasites have been found in 9 of 108 almost consecutive autopsies at Manila, and in 6 of these the naked-eye conditions, taken with the symptoms, seemed to justify a certificate of death from cardiac beri-beri or acute dilatation of the heart. The number of heterophyid worms present in the lumen of the intestine was small, and no eggs were seen in its contents; but such examinations do not disclose the weight of infection, for if the mucosa is scraped successive collections of flukes can be made, and sections show them in the intestinal wall with little reaction around them. Further examination was made of the heart muscle of these persons, and in it were found not only at least one fluke but a number of eggs ranging from $16 \times 10 \mu$ to $33 \times 25 \mu$ according to the species of trematode; they lay in spaces apparently caused by rupture of muscle-fibres and containing also blood and much oedematous fluid. It is thought that the sequence was embolic blocking of capillaries by eggs from the intestine, followed by violent spasmodic contraction and breakage of the muscle-fibres. No investigation of other organs or tissues was made at the time; but if the eggs reached the coronary arteries by the circulation they must equally have reached other parts, and in that case it will be surprising if they are not found to produce in them symptoms which are at present being overlooked. In order to separate this infection from cardiac beri-beri in those countries where raw fish is eaten there is a wide and seemingly profitable field of research; but it can be no easy one if, as stated, eggs are absent from the faeces when there is infection with these particular heterophyids. The lesions must be caused by side-tracked individuals which can by no means carry on the race, but have apparently become more dangerous to man.

TREATMENT OF INTUSSUSCEPTION

ON another page of this issue Mr. Elliot-Smith argues persuasively in favour of a conservative attitude towards irreducible intussusception. Instead of trying to remove the mass, in part or whole, he would merely relieve the obstruction by a lateral anastomosis, and he is able to record good results from this relatively safe operation. It is interesting to learn from a monograph¹ by Gullichsen, of Helsingfors, that even more conservative measures have lately taken on a new lease of life in Scandinavian countries, chiefly because of the new possibility of controlling its course and observing its results by means of radiography. Gullichsen traces the history of the method since Olsson and Pallin published four successful cases in 1927. In one, at which he himself assisted, the barium enema was injected primarily for diagnostic purposes but proved accidentally therapeutic. A general anaesthetic is not usually necessary; the child is held firmly on the X ray table. The enema is then administered and the container is gradually raised so that the pressure of the fluid reduces the invagination. The distended ileum may mask the final few inches, and abdominal manipulation may be needed to bring it into view. The reduction should be gentle and gradual, and takes about 10-15 minutes. Violent pressure should not be used, and, if there is any doubt about success, open operation should be resorted to without delay. Gullichsen speaks of four tests of disinvagination. (1) With an incompetent ileocaecal valve, the opaque fluid can actually be seen entering the small intestine. (2) When the ileocaecal valve is competent, the smooth and regular outline of the distended caecum is to be looked for; any irregularity of the inner border is presumptive evidence of incomplete reduction and calls for operation. (3) The calmness of the child is further proof of a return to normal. (4) Expulsion of gas after the evacuation of the opaque enema is a valuable sign of success. The objection to non-operative treatment is that it can be useful only in early cases and may lead to delay. Where operation is required and the intussusception cannot be reduced Gullichsen is on the whole in favour of rapid resection. But Mr. Elliot-Smith is certainly right in saying that this is very dangerous to young children.

THE NOBEL PRIZE FOR MEDICINE

It is announced from Stockholm that Dr. Hans Spemann, professor of zoology at the University of Freiburg in Breisgau (Baden), has been awarded the Nobel prize for medicine. Spemann and his school have been doing fundamental work in experimental embryology since the beginning of the century. He has been concerned particularly in demonstrating the energising action of certain parts of the embryo on others: for example, the action of the optic vesicle in promoting lens formation, the organising power in the dorsal lip of the blastopore, or the self-orientating properties of the growing auditory vesicle. Such investigations led, of course, to more intricate experimentation and the formulation of more or less definite hypotheses concerning regulation of growth and the potencies of embryonic parts, whatever might be their presumptive fate ordinarily. These researches open up important questions of growth and differentiation, and have already profoundly

modified our conceptions of normal and abnormal bodily processes.

Dr. R. M. F. Picken, professor of preventive medicine in the Welsh National School of Medicine, has been appointed by the Health Organisation of the League of Nations as representative of Great Britain on an American study tour, which begins at Washington on Nov. 4th and ends in New York on Dec. 7th.

On Tuesday, Nov. 5th, Dr. Daniel T. Davies will deliver the Bradshaw lecture on peptic ulcer at the Royal College of Physicians of London. On Nov. 7th and Nov. 12th Dr. J. D. Rolleston will give the FitzPatrick lectures, speaking on the history of the acute exanthemata. The Lloyd-Roberts lecture will take place on Nov. 14th when Dr. C. G. Seligman, F.R.S., will speak on the Roman Orient and the Far East. All the lectures will be given at 5 p.m. at the College, and members of the medical profession will be admitted on presentation of their cards.

Mr. William Adams Frost, who died on Oct. 25th at the age of 82 years, was consulting ophthalmic surgeon to St. George's Hospital and consulting surgeon to the Royal Westminster Ophthalmic Hospital. He was joint author with Brudenell Carter of a popular student's manual, and just forty years ago brought out an atlas of the fundus oculi, which was the first thing of its kind.

BRITISH POSTGRADUATE MEDICAL SCHOOL.—A refresher course for general practitioners will be held at this school from Nov. 18th to Nov. 30th. Besides members of the staff lecturers will include Mr. R. T. Payne, who will speak on the treatment of varicose veins and varicose ulcers, Dr. Alexander Joe (infectious fevers), Prof. F. J. Browne (toxæmia of pregnancy), Dr. C. W. Buckley (chronic arthritis and sciatica and lumbago), Mr. Sydney Scott (earache), Dr. H. Crichton-Miller (psychology in general practice). During the course sessions will be held at the National Hospital, Queen-square, the Royal London Ophthalmic Hospital, City-road, and the Hospital for Sick Children, Great Ormond-street. Further particulars will be found in our advertisement columns.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Arrangements have been made for the following all-day courses to be held: urology at St. Peter's Hospital (Nov. 4th to 16th); medicine, surgery, and gynaecology at the Royal Waterloo Hospital (Nov. 11th to 23rd); proctology at St. Mark's Hospital (Nov. 25th to 30th). Afternoon courses will include venereal disease at the London Lock Hospital (Nov. 18th to Dec. 14th); infants' diseases at the Infants Hospital (Nov. 25th to Dec. 7th); dermatology at the Hospital for Diseases of the Skin, Blackfriars (Nov. 25th to Dec. 7th). A week-end course in gynaecology will be given at the Samaritan Free Hospital for Women on Nov. 16th and 17th, and another on chest diseases at the Brompton Hospital on Nov. 30th and Dec. 1st. A clinical and pathological course for M.R.C.P. candidates will take place at the National Temperance Hospital on Tuesday and Thursday evenings at 8 p.m. from Nov. 26th to Dec. 12th. A debate on maternal mortality will be held at the Royal Society of Medicine at 8.30 p.m. on Wednesday, Nov. 13th, when Dame Janet Campbell and Prof. J. Munro Kerr will propose the motion that the present rate of maternal mortality is a discredit to modern obstetrics and Prof. Gilbert Strachan and Prof. Daniel Dougal will oppose it. All members of the medical profession will be welcome at the debate, for which no admission tickets are necessary. Further particulars may be had from the secretary of the Fellowship at 1, Wimpole-street, W.1.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LXXV.—PROGNOSIS OF GASTRIC AND DUODENAL ULCER

THE difficulties of diagnosis in patients suffering from gastric and duodenal ulcer have been largely overcome by modern technique in radiology, and it is now possible to detect chronic peptic ulcers with a considerable degree of certainty apart from the occurrence of hæmatemesis, melæna or perforation. In consequence many patients who in former years were diagnosed vaguely as some form of dyspepsia are now known to be cases of peptic ulceration. Moreover, there have been considerable advances in the treatment of peptic ulcer both by medical and surgical means. In consequence, experience on which to base the prognosis of ulcers diagnosed and treated by modern methods is relatively limited, and most of the earlier statistics on the subject are of little value.

Acute Ulcers

Peptic ulcers, whether gastric or duodenal, may be classed as either acute or chronic. Speaking generally, patients with an acute ulcer have little or no history of dyspeptic symptoms, and the diagnosis often only becomes apparent as the result of some sudden catastrophe such as hæmorrhage or perforation. The prognosis with acute ulcers is on the whole far better than in the case of the chronic variety. Although hæmorrhage may be severe it is seldom fatal, and the ulcer has a natural tendency to heal under the influence of rest and suitable diet. Acute ulcers are probably infective in origin, and provided that any septic foci, such as teeth or tonsils, are dealt with the patient may never have any recurrence of symptoms. The actual mortality from hæmorrhage due to an acute ulcer is probably between 2 and 4 per cent. of patients who develop this complication. Many acute ulcers may ultimately become chronic as a result of lack of treatment, gastric hypersecretion, or interference with gastric motility.

Chronic Ulcers

The prognosis of chronic peptic ulcer may be considered from two points of view: (1) mortality, and (2) morbidity. It must not be forgotten that many patients with chronic ulcers drag out a miserably dyspeptic existence to a relatively advanced age. In connexion with the prognosis as regards mortality, the possibility of a carcinoma developing on a simple ulcer must be considered.

CAUSES OF DEATH

How then may a peptic ulcer lead to the death of a patient? Obviously the two most dangerous and frequent complications of an ulcer are perforation and hæmorrhage. Death from the former is now relatively uncommon, provided adequate surgical treatment is promptly available. Nor are deaths from hæmorrhage frequent in relation to the large number of patients who suffer from chronic peptic ulcers. Probably not more than 20 per cent. of ulcers bleed severely, and of these not more than 5 to 10 per cent. die of hæmorrhage. The age of the patient is an important factor in prognosis. Death from hæmorrhage due to a chronic ulcer is very unusual before the age of 50. On the other hand, there is a much increased risk with elderly patients whose arteries are atheromatous. Patients rarely die unless they have several hæmorrhages

within a short time, and if further bleeding takes place it usually does so within four days. Consequently in cases of severe hæmatemesis it is usually safe to give a good prognosis, at any rate as regards immediate risks, if four to five days have elapsed without recurrence. Modern methods of treatment, especially transfusion, and the disinclination of surgeons to operate when a patient is bleeding have materially improved the prognosis. Pyloric stenosis or hour-glass stomach, both of which may result from peptic ulcer, may endanger life by severe malnutrition or alkalosis. In such cases the results of surgical treatment are usually good.

It is difficult to say with any certainty what proportion of patients with chronic ulcers are ultimately operated upon, but it is probably in the neighbourhood of 25 per cent. The immediate risks of operation are by no means negligible, and in all probability are far greater than the danger of death from hæmorrhage. The average mortality following all operations for ulcer is certainly not much less than 5 per cent., even in the hands of reasonably competent surgeons.*

Apart from the immediate risks of death from operation there are smaller but very definite dangers due to the development of such serious complications as gastrojejunal or jejunal ulcers and gastrocolic fistula. Most surgical statistics suggest that these complications occur in only between 2 and 4 per cent. of patients operated on for ulcer. Physicians who often have to deal with operative failures would probably put this figure considerably higher. The mortality of secondary operations is very high, and the chances of a completely successful result relatively small.

At this point the question of the risk of malignant changes developing in peptic ulcers must be raised. Carcinoma of the duodenum is practically unknown, and patients with duodenal ulcers run no special risk of developing malignant growths. This, however, is not true of gastric ulcer, where undoubtedly carcinoma may supervene on a simple ulcer. How frequently this occurs is a matter in which there is a wide difference in opinion. Speaking generally, most clinicians regard the risk as small, whereas many pathologists take the view that malignant change occurs in a high proportion of gastric ulcers. The main argument against the idea that carcinoma often develops in a simple ulcer is that patients with carcinoma of the stomach rarely give any indication in their past history of symptoms pointing to a chronic gastric ulcer. Whereas most patients who come under treatment for gastric ulcer have obviously suffered from the condition for many years, at least 80 per cent. of proved cases of carcinoma of the stomach have had perfect digestions until a comparatively short time before the presence of a growth becomes apparent. It may therefore be argued that the risk of death from a gastric carcinoma is little greater in patients with peptic ulceration than it is among the general population.

The general conclusions from the facts cited above indicate that the prognosis as regards expectation of life is not very unfavourable in patients known to be suffering from chronic peptic ulcer. It is

* The mortality-rates of the various operations were differentiated in a previous article in this series on the Prognosis in the Surgical Treatment of Peptic Ulcers by Sir James Walton (THE LANCET, 1934, ii., 37).

probably true to say that if 100 patients with proved ulcers, gastric and duodenal, were traced throughout life not more than five or six would be found to die as a direct result of the presence of the ulcer.

MORBIDITY

If we now turn to the prognosis as regards the maintenance of good health and continued freedom from symptoms we are faced with a far more gloomy picture. The frequency of relapses renders the condition serious and sometimes completely disabling. Although both medical and surgical treatment can claim a good proportion of permanently successful results, only too often the tale is one of continued relapses in spite of treatment.

The outlook as regards the rapid relief of symptoms under medical treatment is extremely good. Nearly all patients with uncomplicated ulcers, whether gastric or duodenal, are relieved of their pain within one week of instituting strict medical treatment with rest, diet, and alkalis. Unfortunately the improvement is often not maintained for very long when the patient has returned to a normally active life.

STATISTICS

There have been a number of statistical inquiries into the after-histories of patients who have received medical treatment for chronic peptic ulcers. Some of these date from twenty or more years ago and are of little value owing to the inadequate methods of diagnosis then in use. In more recent statistics the after-history of the patient has been studied for a relatively short period, so that it is difficult to judge to what extent cures have been permanent and complete. One disquieting fact does, however, emerge from the published figures—namely, that the longer the period of observation after medical treatment, the greater becomes the proportion of relapses and the smaller the proportion of complete cures. This indeed is true not only of medical but of surgical treatment of ulcers. Gastrojejunal or jejunal ulcers may develop even ten years or more after operations such as gastrojejunostomy. It is doubtful whether medical treatment effects a complete and permanent cure in over 50 per cent. of cases, whether gastric or duodenal. The value of any statistics in which the patients have been followed up for less than four years is very problematical.

Statistical inquiries, however carefully conducted, into the late results of treatment for gastric and duodenal ulcer, whether medical or surgical, can do little beyond show certain percentages of cures and failures. Such inquiries can be of little help in assessing the prognosis of the individual patient. When faced by the prospect of a long course of dietetic treatment, or perhaps even of an operation, the average patient will find only cold comfort in the fact that a certain percentage will do well and a certain percentage badly. What the patient really wants to know is what are his own chances of a successful result. Is it possible by a careful consideration of the individual patient to form a reliable judgment as to his future progress? On what grounds are we to differentiate between a favourable and an unfavourable prognosis in the individual case?

FACTORS IN PROGNOSIS

Although giving a prognosis is necessarily a hazardous procedure, particularly in a disease such as peptic ulcer, there are certain general principles which are of value.

The first and perhaps the most important factor in assessing the prognosis is the fact that the chance

of a permanent cure varies inversely with the *chronicity* of the ulcer. Peptic ulcers which are diagnosed early—within six months or even a year of the onset of symptoms—are undoubtedly more amenable to medical treatment than are those which have been present for many years. Unfortunately at the present time few patients with ulcers are diagnosed and efficiently treated until they have had a series of relapses, each one longer and more severe than its predecessor. At any rate, with patients of the hospital class it is rare for any serious attempt to be made to treat the patient until the ulcer has been present for many years, and sometimes not until cicatricial changes have produced mechanical derangements, such as pyloric stenosis or hour-glass contraction. Other things being equal, therefore, a short history justifies a good prognosis, while in the very chronic cases with histories of numerous relapses over many years optimism is unlikely to be justified. With increasing clinical knowledge and the increased efficiency of radiology, it is to be hoped that more ulcers may come under strict treatment in their earlier stages. When this happens, the late results of medical treatment should improve.

Another important factor in prognosis is the *age of the patient*. Elderly patients with ulcers, whether gastric or duodenal, are notoriously unsatisfactory, and often even with strict and prolonged treatment the ulcer may fail to heal and recurrences are extremely common. In the case of elderly patients with large gastric ulcers there is always the possibility of malignancy. A fractional test-meal with a high or normal acid curve makes this contingency very unlikely, but even so a large gastric ulcer in any patient over 60 is unlikely to heal satisfactorily under medical treatment.

In assessing the prognosis in patients with duodenal ulcers a very *high gastric acidity* is an unfavourable sign. The ulcer is more likely to recur if the concentration of acid is very great and if such patients have gastrojejunostomy performed there is a considerable risk of gastrojejunal or jejunal ulceration. On the whole duodenal ulcers tend to occur earlier in life than do gastric ulcers, and they usually react more satisfactorily to medical treatment. Ulcers, either gastric or duodenal, which have penetrated deeply, causing erosion of the pancreas or liver, frequently completely fail to respond to medical treatment and require surgical intervention.

The ultimate prognosis also depends to a considerable extent on the *psychology* of the individual patient. Medical treatment cannot be effective without the close coöperation of the patient, and calls for great attention to detail, perseverance, and self-control. Only too often patients with peptic ulcer, particularly duodenal ulcer, are of the active over-anxious type; it is often difficult to persuade such patients of the necessity for a strictly controlled life and régime, once the troublesome symptoms have passed off. The ultimate prognosis must be unfavourable in any patient who is unwilling to amend his ways as regards smoking, alcohol, irregularity of meals, overwork, late nights, and the pleasures of the table. All these factors predispose to a recurrence of ulceration, and if the patient has not sufficient strength of mind to control himself, not only for months but even years, further trouble is almost inevitable. Only too often it needs some dramatic complication, such as a severe attack of hæmatemesis, to render the patient amenable.

Finally the *family history*, the *social status*, and the *occupation* of the patient are important. A history

POST-GRADUATE LECTURES

THE two lectures summarised below were given at week-end post-graduate courses held this autumn in the London teaching schools. Mr. Patterson, whose lecture was illustrated by instruments, radiograms, and drawings, spoke at the London Hospital, and Mr. Gwynne Williams at University College Hospital.

DIRECT INSPECTION OF THE LARYNX, LOWER PHARYNX, LOWER AIR-PASSAGES, AND GULLET

(MR. NORMAN PATTERSON)

FOR the direct examination of the air-passages and œsophagus there are so many different forms of instrument that it is often difficult to select the type best suited for a particular case. In dealing with the laryngopharynx and larynx, instead of a tubular laryngoscope, I prefer some form of suspension apparatus or directoscope. With such an instrument both hands are free for manipulations, binocular vision is often possible, and the biting-out of a piece of tissue for biopsy or the removal of an innocent tumour can be carried out with great precision. Employing a suspension instrument a tumour or cyst can sometimes be removed accurately by dissection. In working at a lower level a bronchoscope with terminal illumination offers many advantages over one which carries a light at its proximal end. With such an instrument manipulation with forceps is greatly facilitated and it is much easier to gauge the relationship of the forceps to the distal end of the tube. In some cases tubes fitted with a lens, and giving a magnified view of structures, are useful.

In this country there is still a great deal of prejudice against the direct examination of the air-passages with the bronchoscope. If properly carried out, a bronchoscopy is, unless there is some definite contra-indication, practically free from danger; even in the presence of serious disease in the lungs, provided no general anæsthetic is administered, the risk is infinitesimal. If bronchoscopy were performed as frequently as it ought to be no doubt many negative findings would have to be recorded; a report that the bronchial tree is healthy may, however, be useful to the physician.

Recently I paid a very short visit to Philadelphia and I had the pleasure and honour of being shown over the Temple University Hospital Clinic by Dr. Chevalier Jackson, a man who by his genius and untiring energy has done more for the science and

art of bronchoscopy than any other worker in this field. I also had the advantage of visiting the clinics of Drs. Tucker and Clerf. The amount of work which is being done at these clinics is simply astounding. The diagnosis and removal of foreign bodies, of which there are a very great number, forms but 2 per cent. of the total number of cases.

It is rather a common fallacy that, apart from dealing with foreign bodies, there is not much of a field for the endoscopist. I will mention only a few of the conditions which may call for bronchoscopic inspection; they include dyspnoea due to tracheal or bronchial obstruction, certain cases of atelectasis, bronchiectasis, abscess, obscure cough, wheezing, asthma, and so forth. In Philadelphia the most delicate operations are carried out in children, no anæsthetic being employed. Even in infants it is sometimes found necessary to pass a bronchoscope.

It is interesting to note that early in the century Brünings, a pioneer in the subject, stated that the use of a tube of less than 7 mm. diameter was impracticable, and if the child's larynx was too small to admit a tube of this size investigation must be made through a tracheotomy opening. Now tubes of 3 mm. or even less are employed.

Associated with the rapid progress made in bronchoscopy much has been done by physicians, and the name of McCrae deserves special mention in connexion with the symptomatology and physical examination of the chest in foreign body cases and those due to disease. It must be admitted that occasionally a foreign body may be present in a bronchus with a complete absence of either signs or symptoms. Such a case was admitted to the London Hospital a short time ago, when I removed a metallic body, visible of course on X ray examination, from the bronchus of a child. Careful physical examination revealed no changes in the chest. A foreign body may also lodge in the œsophagus and give rise to no signs of its presence or cause misleading symptoms referable to the air-passages. There are various symptoms which point to partial obstruction of a bronchus or to a foreign body which is moving about in the tracheobronchial tree. Adventitious sounds may then be produced. For instance, the impact of a body against the sub-glottic region may produce a characteristic noise. I have met with two cases in which children aspirated portions of toy musical instruments. The active part of the instrument in both cases continued to function while lying in the bronchus and a whistling noise could be heard at some distance.

Many interesting chest conditions result from the presence of foreign bodies. Owing to movement of an object to a new position, sometimes on the other side of the chest, the physical signs may undergo sudden alterations. With regard to the effect of a foreign body on the thoracic contents much depends on its position, relative size, and composition. Organic bodies are liable to cause irritative and inflammatory changes. In estimating the importance of the changes found on physical examination the anatomy of the bronchial tree must be kept carefully in mind, and of course an intimate knowledge of the anatomy of this region is necessary to the successful radiologist and bronchoscopist. A tumour occupying a bronchus or one of its branches will produce symptoms in many respects comparable to those caused by a foreign body. Symptoms and physical signs will vary with the situation, attachment, whether

(Continued from previous page)

of peptic ulceration in other members of the family is not very uncommon and is an unfavourable prognostic point. Patients who are financially independent do better than those who have to worry about an early return to work, as the former are more likely to be able to afford the necessary time and expense for thorough treatment. Any occupation which involves a life with irregular or hasty meals, does not conduce to permanent cure. This is well exemplified by the frequency of duodenal ulcer in the medical profession.

J. J. CONYBEARE, M.D., F.R.C.P.,
Assistant Physician, Guy's Hospital.

sessile or pedunculated, and amount of obstruction caused by the tumour.

It is easy to demonstrate by X rays an opaque foreign body. When the body is non-opaque, areas of increased dullness or translucency or the presence of displacement of the heart and diaphragm may point to the existence of a foreign body. I cannot here go into all the various uses to which the bronchoscope may be put; I will only mention one condition where bronchoscopy may prove of the greatest help. It is well known that a large proportion of malignant growths of the lungs start in the larger bronchi. The early symptoms are insignificant and it may be impossible to make certain of the diagnosis without a direct visual examination. Occasionally a tumour which has all the appearances of malignancy turns out to be of an innocent nature and its removal may result in a complete cure. The tumour may prove to be due to some other cause such as chronic inflammation, tubercle, or syphilis. A stenosis or distortion of the bronchial wall may be produced by an extramural tumour.

To the thoracic surgeon a report by the bronchoscopist may be indispensable. It may indicate the extent and nature of the operation to be performed or it may reveal a condition which cannot be dealt with surgically. In inoperable cases the insertion of a radon container or radon seeds has been followed by relief which may extend over years.

Œsophagoscopy should be employed in the removal of all cases of foreign body in the gullet with the exception of bodies which have passed through the wall of the tube into the tissues of the neck. The most common form of œsophageal obstruction is unfortunately due to malignant disease, and here treatment with radium or by radical surgery has been almost a complete failure. The best that can be done is generally an early gastrostomy.

There are many other causes of œsophageal obstruction, some of which lend themselves to treatment. Fortunately, in this country stricture due to the swallowing of lye, which is common in American children, is practically unknown.

SURGICAL TREATMENT OF ARTERIAL OBSTRUCTION IN THE LEG

(MR. GWYNNE WILLIAMS)

A FEW years ago the only surgical treatment of these defects of the arteries of the lower limb would have been the performance of an amputation, usually a major one above the knee-joint, to deal with a fully developed gangrene. Now operations designed to paralyse the sympathetic supply to the limb offer some hope that the death of the part may be prevented, or at any rate postponed, and the comfort of the patient promoted.

In a limb in which the vessels are normal, such as the cold leg of a patient who has been paralysed by anterior poliomyelitis, the excision of the lumbar sympathetic cord will produce a permanent change. The skin of the limb will be warm from the middle of the calf downwards and the patient is saved from the painful foot and chilblains which every winter has brought. Such a perfect result could not be hoped for in a limb in which the vessels are diseased. Various methods have been tried in order to test beforehand whether paralysis of the sympathetic will bring about the desired result: they include injection of foreign proteins, spinal analgesia, anaesthetisation of the peripheral nerves, and the warming

of the patient while the affected part is kept outside the direct influence of the heat. These tests undoubtedly in many cases enable a forecast to be made of the effect of sympathectomy, and if any of them is to be used the last is the preferable method. Spinal analgesia is not a procedure to be lightly undertaken; I have had considerable experience of it and it is not devoid of risk. At present my impression is that in some cases in which the tests predict the failure of a sympathectomy the operation will be followed by success.

The next question is as to which of the clinical features of arterial obstruction will be affected by the sympathetic paralysis. The only changes which we can directly observe are those in the skin: the foot will become warmer and will lose its blue-red colour; small patches of dead skin will separate and indolent ulcers will heal.

The other conspicuous feature of the obstruction—namely, intermittent claudication associated with a deficient blood-supply to the muscles—does not seem to be so certainly influenced. This might be expected if it is true that the vessels of the muscles are not dilated after sympathectomy. There are cases in which the patient who has had the sympathetic removed is able to walk further without suffering pain, and the analogous relief of angina pectoris by removal of the stellate ganglion make it desirable that further observations should be made on the results of such operations.

I have here to-day a patient of 56 who came to the hospital eighteen months ago complaining of intense pain in the right foot, which she had had for three years. The foot was red-blue and cold, and her toes were so tender that she resented their being touched. There was a small patch of gangrene on the tip of the big toe. At first glance the case seemed eminently suitable for a lumbar sympathectomy, but a further examination showed that she had a systolic blood pressure of 250 and that her heart was in such a condition that it was doubtful whether that operation would be justifiable. Something had to be done for her pain since it prevented her from sleeping, so I injected some 50 per cent. alcohol into the posterior tibial nerve behind the malleolus and a few days later into the peroneal nerves in front of the ankle. I was hoping to produce a temporary anaesthesia and possibly a more permanent sympathetic paralysis. The immediate effect was naturally a loss of the pain associated with the analgesia and the foot became warmer and of a more normal colour. The dead patch separated, the skin healed, and the patient went out relieved of her symptoms although the anaesthesia had disappeared a few weeks after the injection. This relief of symptoms lasted for a year, after which she returned with her foot in the condition which she had originally shown. I again attempted an alcohol injection but failed to hit off the nerves, so a month ago I cut down on the nerves and excised an inch from each of them. The operation wounds have healed slowly, indicating the deficiency of the circulation; but her foot, while slightly pinker than the opposite one, is almost normal in colour.

The improvement in the circulation must be due to local paralysis of the sympathetic and this and the sensory nerve action have relieved her pain. I have succeeded in two other cases with the alcohol injection, but it is not always possible to hit off the nerve, and it is better to excise a portion of the nerves.

Perhaps I have said enough to show you that

SPECIAL ARTICLES

ELECTRIC SHOCK AND SUBJECTIVE SENSATION

IN RELATION TO ANÆSTHESIA AND HUMANE SLAUGHTER

By C. W. HUME, M.C., B.Sc.

HON. SECRETARY, UNIVERSITY OF LONDON ANIMAL WELFARE SOCIETY

WHEN an electric shock is strong enough to make a person inert, he usually becomes unconscious almost at once; but cases have been known in which persons, apparently unable to move or speak, have retained both consciousness and sensibility to pain. It is naturally difficult to discover what are the chances of this happening. With accidents the conditions cannot be controlled beforehand, and the information available afterwards is apt to be scanty and lacking in precision. Deliberate experiment, on the other hand, is restricted by the risk of fatal consequences.

The data summarised in this article were collected in the hope of throwing some light on the question whether the use of electricity as a preliminary to the slaughter of animals for food is, in fact, a reliable means of producing unconsciousness. I hope, however, that they may have a more general interest.

FACTORS WHICH DEFINE THE ELECTRICAL STIMULUS

In electrical accidents it is usual to regard the voltage as the factor that determines the strength of the shock, but actually the voltage gives very little indication of the real strength of the stimulus. The only electrical factor which really matters is the current-density at some crucial point in the organ affected.¹ It is conceivable that the direction of the current with respect to the axis of the vulnerable organ may also affect the results, but so far as I am aware there is no experimental evidence that it does so.

The current-density depends on a number of factors, one of which is the voltage. It must be remembered, however, that by far the greater part of the voltage-drop occurs at the contact of the electrodes with the skin, and that the resistance at this region is not only very high but very variable. The hand-to-hand resistance of a human being is usually reckoned as a few thousand ohms, but if the resistance of the skin itself be eliminated, the remaining resistance—that of the deep tissues—amounts to

¹ By current-density is meant the amperes per sq. cm. of cross-sectional area.

(Continued from previous page)

something can be done surgically for this arterial deficiency; but I must emphasise the fact that these measures are not likely to be successful when any mass of tissue has died, and that it is therefore essential that the pre-gangrene condition should be recognised.

The pre-gangrene changes have been most widely observed in thrombo-angiitis obliterans, since in this condition the progress of the disease is slow; but if sought for they will be found in the arterial change associated with raised blood pressure, old age, and diabetes. In these conditions any treatment which holds out the promise, however faint, of avoiding the mutilation of a major amputation should be tried.

only about 200 ohms. When, therefore, we remember that the dampness of the skin, and consequently its conductivity, varies greatly from person to person, we shall see clearly that the voltage between the electrodes no more indicates the strength of the shock to which a person is subjected than the horsepower of a car indicates the speed at which it is travelling. Cases are known in which a workman has for a wager subjected himself to a shock of 500 or 1000 volts: the trick consists in first drying the hands with methylated spirit. On the other hand, it is generally held that 50 volts alternating current is capable of causing death.

It is impracticable to measure the current-density at each point in the body or the brain. The nearest, in practice, that we can get to specifying the strength of the electrical stimulus is to state the size of the animal, person, or part affected, together with the amperage, if possible, or failing that, the factors which determine the amperage—namely, the voltage, the state of the skin (moist or dry), and the pressure or firmness of contact between the electrodes and the skin. In other words, the current-density depends upon the amperage and on the size of the part through which the current spreads out. The amperage in turn depends upon the voltage and on the resistance in circuit. The resistance depends mainly on the size of the electrodes, the dampness of the skin, and the firmness of contact between the electrodes and the skin.

The next most important factor in the electrical stimulus is the wave-form. It is well known that when a potential-difference derived from a battery is applied to a muscle or nerve, the reaction is considerable at the moment when contact is made or broken, but is inconsiderable so long as the current is merely left flowing. In other words, it is the rate of change of direct current rather than the strength of the direct current itself that is of physiological importance. For this reason a shock from direct-current mains is far less effective than a shock from alternating-current mains; for alternating current consists of a direct current whose strength varies continuously at the rate of about 50 cycles per second, passing from a maximum positive to a maximum negative value and back again in each cycle. In other words, it is a direct current whose strength is constantly changing.

Another type of current which has to be considered is the intermittent direct current produced by interrupting the current from a battery say 100 times per second, the current being left on for one-tenth of each cycle and turned off for the remaining nine-tenths. With an alternating current the strength changes smoothly from one extreme to another, passing through all intermediate values; but with an intermittent direct current the changes are sudden. Hence we should expect that for a given current-strength the intermittent direct current would have considerably more physiological effect than the alternating current. This expectation is fully borne out by experiments on pigs. The strength of alternating current which is usually recommended in this country in a slaughter-house for pigs is roughly 800 milliamperes, but Regensburger obtained precisely similar results with intermittent direct current of the order of one-twentieth of this amount.²

² Details are given in the Animal Year Book, 1935, vol. iii., chap. 7 (Univ. London Animal Welfare Soc., 42, Torrington-square, W.C.1).

It has been customary, in cases where the current strength was measured at all, to give simply the reading of a milliammeter in series with the animal, but this procedure is misleading to those who are not electricians. For instance, with an intermittent direct current the reading of the instrument can be increased by leaving the current on for two-tenths or three-tenths and off for eight-tenths or seven-tenths of each cycle; and if this is done the increase in the reading of the milliammeter bears no relation to the increase in the strength of the stimulus.

It must be remembered that an ammeter does not record the instantaneous value of the current, which varies far too rapidly to be indicated by any instrument other than an oscillograph. The ammeter records the mean current or more usually the root-of-mean-square current, and the foregoing remarks apply to the changes of instantaneous current which would not be indicated by an ammeter.

At the risk of undue repetition, it is desirable to emphasise the fact that "mean current-strength" may have two different meanings, for confusion often arises in the non-electrical mind on this point. The instantaneous values of a current varying at, say, 50 cycles per second have a mean which is recorded by the ammeter. This must be distinguished from the mean of a series of ammeter readings.

If, however, the current-strength is increased while the wave-form is kept unaltered, we have to consider whether most effect is produced by making the increase all at one stroke, or by carrying it out step by step. It would appear that the step-by-step method is likely to be less effective than the all-at-one-jump method. This remark applies to those changes of mean current-strength which are made so slowly as to be observable on an ammeter.

Another factor which determines the strength of the stimulus is the frequency of the current. Increasing the frequency from 50 cycles to 100 cycles per second makes very little difference to the effectiveness of the stimulus; but if the frequency is increased to hundreds of thousands, or millions, of cycles per second the results are totally different. The nerves and muscles have no time to respond and the only noticeable effect is the development of heat in the tissues. It is for this reason that in electrothermal treatment high-frequency currents may have a strength very much greater than that which would be fatal if the current were of low frequency.

PASSAGE THROUGH HEART AND BRAIN

We have next to consider the point at which the electrodes are applied and the path which the current follows. Kouwenhoven³ has shown that the current has a specific effect on the organ through which it passes, and the organs which we have to consider are the brain and the heart. It must be borne in mind that the current does not flow along a straight line from electrode to electrode but spreads out in all directions into the tissues, being strongest in the direct route from electrode to electrode, but weaker and weaker at points that lie further and further off this route.

Kouwenhoven showed by direct measurements that when a current was passed from the fore limbs to the hind limbs of a dog, 10 per cent. of it passed through the heart. A comparatively weak current, he found, would produce fibrillation which lasted until death ensued. A comparatively strong current on the other hand caused complete stoppage, but after an interval the heart again began to beat either of its own accord or after restorative action. It has therefore been proposed that where a person's

heart has been sent into fibrillation by electric shock, any curative treatment should be preceded by a second shock sufficiently strong to stop the irregular action. In most electric accidents it is the effect of a current passing through the heart that has principally to be considered, whereas in the slaughter-house we are concerned with the effect of passing current through the brain. This effect is twofold. In the first place the muscles of the whole body are strongly stimulated; if the current is strong enough vertebrae may even be fractured by the violence of the muscular contraction. For this reason, if for no other, the use of electric stimulation as an alleged anaesthetic for surgical operations is to be deprecated. In the second place the current inhibits breathing, so much so that artificial respiration has normally to be applied after electric shock. The most important point to observe is that an animal can be rendered inert and apparently unconscious for several minutes by a shock which leaves no detectable lesions in the brain. If it is allowed to recover, its behaviour may become perfectly normal; so that, whatever the cause of the muscular contraction, immobilisation, and inhibition of breathing may be, this cause does not consist in any damage to the brain. After brain shocks caused by strong currents cerebral lesions may be found; but the current-density necessary to produce such lesions is substantially greater than that used in the slaughter-house.

SUBJECTIVE EXPERIENCES IN ELECTRIC SHOCK

As a rule electric shock occurs in such a way that the current passes through the trunk, and therefore through the heart. If unconsciousness is not immediately produced, the victim's sensations are a sense of burning and of pain due to excessive stimulation of the muscles. Usually, however, he becomes unconscious at once.

More difficult and more interesting is the question at what stage unconsciousness ensues when currents of moderate strength are passed through the brain. So far as I am aware there is no case on record where unconsciousness has been caused in a human being by the passage of current through the brain alone, unless that current was strong enough to inflict actual damage on the brain. Ledue, in 1902, in trying to find an electrical method of anaesthesia, allowed a current to be passed through his head, with the result that his assistants supposed him to be completely unconscious for twenty minutes. As soon as the current was turned off, however, he was able to say that he had been continuously and fully aware of all that was going on. The current used in his case was very weak. More recently, in 1925, Dr. Hertz⁴ at the Rothschild Hospital in Paris made similar observations on patients with incurable disease. His currents were considerably stronger; in fact, when allowance is made for the difference in wave-form the stimuli he used were almost as strong as those commonly employed on pigs in the slaughter-house. But they were not quite so strong, for the subjects recovered their mobility as soon as the current was turned off, whereas pigs usually remain paralysed for half a minute or more afterwards. All of Hertz's subjects retained consciousness throughout the experiments and were able to indicate the places where they had been pinched. The current was raised to a strength sufficient to stop their breathing for a short time. The pupil reflex was inhibited, but not other reflexes;

³ Kouwenhoven and others. The following papers may be consulted: *Elect. Eng.* (New York), 1930, xlix., 25; 1931, l., 406; 1933, lli., 475; *Jour. Indust. Hyg.*, 1932, xiv., 197.

⁴ Hertz, J.: *Rev. de path. comp.*, 1933, xxxiii., 385.

all voluntary motion was inhibited. Thus the tests gave results generally similar to those which were applied when the present system of electric "stunning" was pronounced to be humane.

Electrical accidents may throw some light, albeit a very uncertain light, on the problem; but they suffer, as I have said, from the disadvantages that we cannot choose the conditions under which they will occur and that quantitative data are usually very incomplete. I have however collected a number of instances from electrical engineers who have suffered shock, and have described a few cases in full elsewhere.² They prove that it is possible to retain the sense of pain, which may be severe, while speech is inhibited.

The whole subject is one which calls for very thorough study. In view of the commercial vested interests and the partisanship which have become involved, assertions have to be carefully tested in the light of evidence; and usually it will be found that the evidence is inconclusive. I am aware of at least one laboratory where electric immobilisation is being used for the purposes of producing anaesthesia, though fortunately for experiments which would not in any case be particularly painful. In many slaughter-houses in this country and throughout the world the system is in use in the confident belief that it produces genuine anaesthesia. Considering the scantiness of the really reliable data this is a very unsatisfactory state of affairs.

How the question is ever to be settled it is for physiologists to decide. So far as I am aware they cannot at present say why or how an electric current acting on the brain produces the effects that it does produce. These effects seem to differ in certain respects from those produced by an ordinary anaesthetic, and I venture to suggest that superficial tests carried out with a few commercial instruments should not be regarded as sufficiently radical to justify the use of electricity for anaesthetising animals.

MEDICINE AND THE LAW

Use of the Description "Manipulative Surgeon": A High Court Decision

LAST November the Paignton magistrates dismissed summonses under Section 40 of the Medical Act against Captain Horace Barrow, described as a bone-setter, who had used the title of "manipulative surgeon" after his name on the gatepost of his house and on his motor-car. When invited by the Medical Defence Union to justify or discontinue these words he replied that he was not using the title of "surgeon," and would not give up the description on his plate until it was proved that he was not a "manipulative surgeon." As we pointed out at the time (1934, ii., 1186) the Medical Defence Union was not contending for a monopoly of medical or surgical treatment; Captain Barrow was not summoned for manipulating his patients' limbs, but simply for the adoption of a description which blurred the distinction made by the Medical Act between qualified and unqualified practitioners. An appeal against the decision was heard in the King's Bench Division on Oct. 25th, when Captain Barrow's counsel contended that the title "manipulative surgeon" had been used for at least 20 years to describe a person not registered under the Medical Act, 1858, who could manipulate bones and joints for the purpose of healing. Lord Hewart in delivering judgment said it was proved or admitted that

Barrow had outside his house a plate bearing his name and the words "manipulative surgeon." He was described in like terms on his motor-car and in the telephone directory. He was not registered under the Medical Act, nor was he a qualified medical practitioner within the meaning of that Act. Captain Barrow had expressed his willingness to adopt some other name to describe his work if another name could be found which would properly describe it. "It is quite obvious," said Lord Hewart, "that there are other names which would fulfil that purpose, as, for example, the words 'manipulative healer.'" If Captain Barrow desired to represent that he was not a qualified surgeon it was unfortunate that he should choose the description "surgeon." The thing which made that name appear to be attractive and useful was, said Lord Hewart, precisely the thing Section 40 of the Medical Act, 1858, was enacted to prevent. The appeal, he said, must be allowed and the case sent back to the justices with the direction to find that the offence which was charged had been proved. After delivering his formal judgment, Lord Hewart added: "Speaking for myself I cannot imagine any adjective which, being added to the title 'surgeon,' would excuse the use of the word 'surgeon' by a person not registered or recognised as a surgeon under the Act of 1858 unless, as in the case of a veterinary surgeon, he is expressly protected by statute." Justices Humphreys and Singleton concurred.

Failure of Bruno Hauptmann's Appeal

The full report of the judgment dismissing Bruno Hauptmann's appeal from his conviction for murder in the Lindbergh baby case has now arrived from America. This sensational trial, which led to a special law being passed against kidnapping, has less medico-legal interest than might have been expected. It had been rumoured that the appeal would be fought on a denial of the identity of the missing baby with the dead body which had been found buried not far away from the Lindberghs' home. The rumour proved false. The defence at the original trial had announced that the identity of the corpse was not challenged. To spare the mother's feelings, questions relating to identification were not put to Mrs. Lindbergh in the witness-box; the police were, in any event, prepared to establish identity beyond all doubt. If a slight overlapping of one of the baby's toes was inconclusive, Col. Lindbergh had been satisfied by examination of the teeth of the dead body, since, shortly before the child was kidnapped, he and Mrs. Lindbergh had very carefully inspected the teeth and had noted certain peculiarities. Another point of identity was the unusual size of the opening of the fontanelle; and, finally, the hair from the head of the disinterred body could have been proved identical with a lock of hair which the child's grandmother had cut from his head. The appellate court of New Jersey announced that a verdict of "Guilty" was inevitable in view of (a) Hauptmann's possession and use of the ransom money, (b) the handwriting of the notes in which the ransom was claimed, and (c) the identification of wood used in the ladder abandoned by the criminal near the Lindberghs' house with wood taken from Hauptmann's own house. This last point was established by patient and skilful research.

The delay in bringing on this American appeal is in contrast to the swift procedure in our English Court of Criminal Appeal. The papers in Hauptmann's case were, however, voluminous and the

appeal was set down too late for the spring session of the New Jersey "Court of Errors and Appeals." Among the many grounds relied upon by the appellant's counsel were (1) that the dead child's father (with other prominent persons unconnected with the case) was present in the court throughout the trial, (2) that there were frequent demonstrations of laughter and applause by spectators, (3) that messengers and clerks disturbed the proceedings, and (4) that press reports and radio broadcasts were made freely. The appeal court found no substance in these matters, especially as no protest was made at the time. Another unsuccessful ground of appeal was that the jury had been allowed the use of a magnifying glass. "We see no more objection to this," said the court, "than to the use of eyeglasses by an individual juror." The judges further declined to accept appellant's contention that the opinion of handwriting experts, based on mere comparisons, "must be esteemed proof of low degree." In its general procedure and legal attitude the New Jersey court is but little different from an English court; but there is one striking exception. For ancient and historical reasons, based partly on mistrust of lawyers and partly on suspicions of the judges appointed by the Crown in the early days of the colony, the New Jersey Court of Errors and Appeals includes lay judges; the nine fully qualified lawyers on the bench had four laymen as their colleagues on this occasion. In one other respect there was a further difference. The Attorney-General of New Jersey, when addressing the jury finally on behalf of the prosecution, was said to have expressed his personal belief in Hauptmann's guilt and to have used vituperative words about him. The appeal court took no notice of this; protest should have been made at the time; moreover, counsel for Hauptmann has expressed a personal belief in his innocence. In an earlier New Jersey case, cited on the appeal, a prosecuting counsel had described a defendant as "a monster in his passions, licentious in his desires, beast in his love, brutal when thwarted, and cowardly when caught." Even these full-blooded denunciations were ruled not to have been a ground for interference with the subsequent verdict.

The failure of all the points raised on Hauptmann's behalf is presumably final. His representatives are said to be considering an appeal from the New Jersey courts to the Supreme Court of the United States. This could only succeed if the Federal Court thought Hauptmann had not been tried, in the famous language of the United States Constitution, with "due process of law"—e.g., if the atmosphere of the trial was so charged with prejudice that the trial was unfairly conducted.

LONDON MEDICAL EXHIBITION

(Concluded from p. 979).

WE gave some account last week of the exhibition in the New Horticultural Hall where nearly 170 stands, adequately displayed, afforded medical practitioners the chance of seeing the best and latest in drugs and pharmaceutical products, the wide choice of new foods and vitamin preparations, and of handling the improved surgical instruments and appliances. A few stands of a more general character remain to be mentioned.

Books and Journals

(21, 22) BAILLIÈRE, TINDALL AND COX (7 and 8, Henrietta-street, W.C.) had a display of medical books from this country and America published by

themselves and other firms, and specially pointed out the fourth edition of Bigger's "Bacteriology"; Griffith's "Injury and Incapacity"; Köhler's "Röntgenology," a new translation of the latest German edition; and the fifth edition of J. L. Livingstone's "Aids to Medicine."—(20) WILLIAM HEINEMANN LTD. (99, Great Russell-street, W.C.) specially selected from their show of books "Woman," in three volumes, by Pless and Bartels, a historical, gynaecological, and anthropological compendium; and also mentioned Souttar's "Radium and Cancer," and the same author's "Art of Surgery"; and the Van de Velde series, of which the latest is "Ideal Birth."—(32, 40, 41) H. K. LEWIS AND CO., LTD. (136 and 140, Gower-street, W.C.), showed their range of medical stationery and furniture, especially the new Unix multiplying book-case unit; and from among their general display of medical books pointed out the catalogue of their lending library and the new edition of the "Extra Pharmacopoeia," ready immediately; the first annual issue of "Reports on Chronic Rheumatic Diseases," edited by C. W. Buckley; Bailey and Love's "Surgery for Nurses," and "A Short Practice of Surgery"; the collected papers of St. Mark's Hospital; a new edition of Moncrieff's "Nursing and Diseases of Children"; and "Urology" by Roche, an addition to the "General Practice" series.—(76) MEDICAL PRESS AND CIRCULAR (8, Henrietta-street, W.C.) showed their popular journal written by specialists for general practitioners, with its symposia and four special numbers on special subjects; also a series of reprinted articles on Modern Treatment in General Practice.—(25) OXFORD UNIVERSITY PRESS (Amen House, Warwick-square, E.C.) drew attention to Russell Brain's "Diseases of the Nervous System"; Samson Wright's "Applied Physiology"; Campbell and Poulton's "Oxygen and Carbon Dioxide Therapy"; and the fourth edition of "Woodward's Manual of Medicine."—(156) THE PRACTITIONER (6-8, Bouverie-street, E.C.) reminded visitors of their valuable monthly journal, and specially pointed out their enlarged issue on recent advances in treatment, and other symposia in special numbers.—(98) JOHN WRIGHT AND SONS, LTD. (Bristol), publishers of the "Medical Annual," showed Böhler's "Treatment of Fractures"; French's "Index of Differential Diagnosis"; Hutchison's "Index of Treatment"; and Semon and Moritz's "Atlas of the Commoner Skin Diseases."

Spas and Miscellaneous

(60) BATH had a stand to remind visitors of the only natural hot springs in Britain, and showed illustrations of their mud pack, hot pool, and thermal vapour treatments, and of the deep bath with under-current douching.—(39) BUXTON said that the most important new feature at this spa is the clinic for patients of limited means which has been open since midsummer. For an inclusive and moderate fee patients can now obtain board, lodging, medical advice, spa treatment, and all necessary pathological investigations.—(178) A. C. COSSOR LTD. (Cossor Works, Highbury-grove, N.5) showed their improved model portable electrocardiograph in which the camera, amplifier, and recorder have now been united in one unit, with a small H.T. separate unit for A.C. or D.C. mains or a car battery. They pointed out the value of their apparatus, which has no string to break, which is protected from all distortion, and which suffers no ill-effects from overloading. They had also a mobile hospital unit designed chiefly for students, as it is visual only and has no camera.—(9) GAS LIGHT AND COKE CO. (Horseferry-road, S.W.) showed some of the newest gas fires for consulting-rooms and wards, with self-lighting switches which may be worked either at the fireside or at a distance; and claimed that the modern fire changes the air in the room four or five times an hour.—(152) HARROGATE informed visitors that short-wave diathermy is an important feature of the service

BRITISH MEDICAL ASSOCIATION

MEETING IN MELBOURNE

SECTION OF OTO-RHINO-LARYNGOLOGY

Mr. F. MUECKE presided over the meeting of this section when Mr. L. GRAHAM BROWN (London) read the opening paper on the treatment of

Chronic Suppurative Otitis Media

He said that the first duty of the doctor was the prevention of chronic middle-ear suppuration. This consisted in (1) teaching rules for diminishing the likelihood of aural infection; (2) its proper care and treatment in the acute stage, especially when complicating exanthematous fevers; and (3) searching for and treating a focus in nose and nasopharynx, or in the mastoid itself. A less generally known cause was latent mastoiditis, especially in young children. This condition might be suspected when an acute otitis media did not resolve in 10 to 14 days, no obvious exciting cause being present. In these cases radiograms were of great value, enabling the surgeon to make a diagnosis, and to intervene before the suppuration became chronic. A simple mastoidectomy was usually quite adequate. The aim of treatment was to deal with the suppurative focus, at the same time preserving maximum hearing. For this reason, conservative measures were first choice and a cure was to be expected in 70 to 75 per cent. of cases. The best response was obtained in those cases where the infection was confined to the atrium of the middle ear, and the perforation was in the centre of the tympanum. Many methods of conservative treatment were available, but the following "wet" method was considered very suitable: the instillation of hydrogen peroxide drops into the meatus, followed by syringing with boric acid solution. This was followed by guttae S.V.R., or pulv. boric. + 1 per cent. iodine. No improvement after 2-3 months in adults, or after 1-2 months in children, usually indicated the necessity for surgical treatment. Minor surgery, to promote better drainage, to allow antiseptics to penetrate, and to remove diseased tissue, cured only a few cases, but was nevertheless justifiable, especially when more radical methods were refused. When planning a major operation, the surgeon had to find the happy medium, and this

would mean dealing adequately with the pathological lesion, but at the same time not unduly diminishing the function of hearing. As the extent of internal damage could often be assessed only at the time of operation, it was best, when the indications were not precise, to proceed conservatively, extending the operation as found necessary. Complete radical operation would be found necessary in most patients suffering from chronic otitis with threatened intracranial suppuration; in those subject to acute exacerbations complicated by facial paralysis of recent onset, or with cholesteatomatous involvement; in those which showed clinically definite sagging of the post-superior meatal wall, and evidence of underlying osteitis; and in those which had resisted conservative treatment.

Simple mastoidectomy was particularly indicated, the speaker continued, in most cases of early chronic suppuration resisting conservative treatment, especially in children when latent mastoiditis had been diagnosed. It would probably also suffice in cases where the tympanic membrane did not appear unduly reddened, but where pus could be aspirated into the cleansed meatus from the antral region, the perforation being situated in the posterior portion of the membrane, even though it were central or marginal. Three points were important in this operation: (1) The incision should be made some distance behind the posterior auricular sulcus. (2) All diseased cells should be opened up. (3) No plastic operation should be performed on the meatus. Mr. Graham Brown had adopted a method of post-operative drainage giving complete satisfaction. About 5 c.cm. of eusol were syringed in through a small tube emerging at the lowermost part of the wound every 1-2 hours during the waking period for 3-4 days. This gave great relief, promoted quick healing, and caused no irritation. Sometimes he used two tubes. A modification of the conservative-radical operation, as first practised by Heath, was used in attic disease. Here, if it was necessary to remove the necrosed incus, it was advisable also to remove the head of the malleus, thereby providing better drainage. During the first week of after-treatment the meatus must be packed firmly with narrow ribbon gauze. Persistent suppuration after operation might be due to faulty technique; skin or muscle grafts, or some plastic form of operation on the meatus might then be found necessary. In conclusion the speaker said that future advance could be expected in better prophylactic measures, and in restoring the mobility of the oval and round windows.

Dr. ROBERT GODSALL (Sydney) favoured conservative treatment for as long as three months or longer if there were favourable indications. He thought zinc ionisation was useful and liked boric powder with 1 per cent. iodine. Polypi should not be removed surgically, but should be cauterised with silver nitrate. Attic syringing was dangerous unless there was a large tympanic opening, as meningitis might result. Vesiculectomy was not indicated; this was difficult to perform and the disease had usually spread beyond the area concerned making cure impossible. "Wet" ears after operation were usually due either to involvement of the Eustachian tube—if this remained patent—or to the outer attic wall being insufficiently dealt with.

Dr. H. J. GRAY (Perth) thought X ray examinations of great help in diagnosing the extent of chronic otitis media, and also in assessing the degree of cure. He thought that swimming was very dangerous in ear infections and that no type of ear pad was efficient.

(Continued from previous page)

offered to patients, and that Fango, the medicinal mud, is yielding very good results. Diet schemes have been drawn up by the medical profession for half a dozen conditions and many of the hotels undertake to enforce them when required.—(110) INHALING DRUG AND APPARATUS CO., LTD. (87, Eccleston-square, S.W.), were present again with their Collison inhaler for the administration of oxygen with vaporised liquids, used chiefly for the treatment of asthma, bronchitis, and pneumonia and also for the nasal passages.—(67) KOLYNOS INCORPORATED (Chenies-street, W.C.) showed their popular dental cream and powder and liquid Kolynos mouth-wash.—(58) MEDICAL SICKNESS ANNUITY AND LIFE ASSURANCE SOCIETY LTD. (300, High Holborn, W.C.) had their usual stand, where they proffered good advice on all kinds of insurance.—(157) SPARKLETS LTD. (93, Regent-street, W.) emphasised their auxiliary atomiser for the Sparklet carbon dioxide hygienator, which provides an economical means of supplying small quantities of any desired solution in a highly atomised form.

He advised surgical intervention in otorrhoea accompanied by much smell, if this latter could not be removed by two weeks' treatment. Syringing was in his view good, but should be done only by a trained person; he used antiseptics before going on to spirit preparations. Surgery had very little value in bilateral otitis. His practice covered a very large geographical area and he thus had to vary his treatment according to what kind of after-care could be performed.

Dr. J. Acomb (York) dealt mainly with prophylaxis; in his opinion little advance in treatment had been made since the introduction of the radical mastoid operation. This operation, he hoped, would become extinct. He advised operation if the hearing was becoming progressively worse. He had seen three cases of preoperative facial paralysis within one month.

Dr. H. M. JAY (Adelaide) mentioned that conductive deafness, without cochlea deafness, was an indication for operation, as this would not lessen the hearing in the ear.

Dr. A. B. K. WATKINS (Newcastle, N.S.W.) treated cases of running ear after an acute otitis media by removing infected tonsils, polypi during the first six weeks, and then doing simple mastoidectomy if necessary. In post scarlet fever otitis he operated earlier.

Mr. J. F. O'MALLEY (London) considered osteitis to be the chief factor, the osteitis being situated mainly in the region of the tympanic ring—except in the case of cholesteatoma. He always tried to treat superficial osteitis, and he gave a better prognosis if he could heal it.

Dr. D. GUTHRIE (Edinburgh) emphasised the importance of prophylaxis, and mentioned the fact that children with an acute otitis media, followed by an acute mastoiditis, seldom developed a chronic otitis.

Dr. C. M. O'HALLORAN (Sydney) said that in spite of prophylaxis very chronically inflamed ears would be encountered. In his experience, a narrow skull was conducive to a running ear.

Dr. J. H. SHAW (Melbourne) said that quick healing and epithelisation might be prevented by excessive and prolonged packing.

Dr. HUGH MITCHELL (Melbourne) mentioned that the ears of slum children admitted for operation after a period in hospital for a time sometimes dried up so that operation was unnecessary. He attributed this to good diet containing fresh fruit and vegetables. Mastoid and chronic otitis media cases, he said, were much more common in England than in Australia, probably for reasons connected with diet.

The PRESIDENT said that the incidence of ear troubles in England had dropped since the removal of septic tonsils had been practised, but the number of chronic otitis media cases was still high, probably due to the neglect of treatment in the earlier stages.

Mr. GRAHAM BROWN, in reply, spoke of the importance of having a mucous-lined cavity after operation to preserve the elasticity of the membranes. He said that the tympanic membrane adhered to the bone because the mucous membrane was destroyed. Exposure was an additional factor in making swimming dangerous in the presence of ear troubles.

A paper on

Sphenoidal Sinusitis and the Pituitary Gland

was read by Dr. CLIVE EADIE (Melbourne). He showed several dissected specimens illustrating the

close relationship of the sphenoidal sinus to the pituitary gland; this relationship, he explained, was the reason why inflammation in the former could readily involve the latter by lymphatic spread. The sinus infection was of three main types: (1) acute, especially in influenza, in which the pituitary was hyperemic and therefore active; (2) chronic catarrhal, in which the pituitary would become involved only during acute exacerbations, or if the process became chronic; and (3) chronic suppurative, when definite pus and organisms were present. *Streptococcus viridans* and *Staphylococcus aureus* were the commonest types of organisms found in a long series of cases. Citelli and Pickworth had demonstrated involvement of the hypophyseal system in sphenoidal sinus disease. Dr. Eadie showed records of 12 cases of sphenoidal sinusitis, associated with pituitary dysfunction, on which sphenoidostomy had been performed. The pituitary dysfunctions included genital disorders, loss of weight, headaches, mental changes, apathy, and epileptic attacks; 10 cases showed improvement after operation, and in 1 case the symptoms were relieved by pituitary extract. Sphenoidal sinusitis was found in 2 cases operated on for pituitary tumour. Records were also shown of 5 post-mortem cases. In 3 of these the pituitary was macroscopically and microscopically normal, in 1 atrophied, and in 1 large with hemorrhagic spots, the sphenoidal sinuses being diseased in each case. Dr. Eadie thought that the importance of this condition was not at present fully realised.

Dr. T. G. MILLAR (Melbourne) read a paper on

Ultra-violet Light Therapy in the Treatment of Laryngeal Tuberculosis

He used a Kromayer lamp, but instead of the usual right-angled applicator he had devised a curved one. His technique was as follows: The throat and larynx were anaesthetised, and the epiglottis hooked forwards by the lamp held in the right hand, with a post-nasal mirror held in the left hand directing the rays exactly on to the lesion. An exposure of from $\frac{1}{2}$ to 5 minutes was used, daily in institutions and weekly in private practice. The dose was regulated so that no subjective symptoms were produced, giving a non-infective inflammation in from 6 to 8 hours. This stimulated healing by fibrosis, killed the tubercle bacilli, and relieved the pain. The rays penetrated only $\frac{1}{10}$ th of a millimetre. Hypertrophic lesions responded better than ulcerative ones, and oedematous types responded least. Only certain cases were suitable. There were two main difficulties: (1) direct current was at present necessary; and (2) an experienced laryngologist must perform the treatment. Dr. Millar then showed records of two cases successfully treated. One mild case healed after weekly exposures for three months. The other, grossly involved, was given weekly treatments for two months and then fortnightly for several months, and eventually the lesion healed completely.

SECTION OF PUBLIC MEDICINE

Sir HENRY GAUVAIN (Alton), president of the section, gave an address on

Sea-bathing

He said that in considering the treatment of surgical tuberculosis, sea-bathing had a very real claim to our consideration. Two pioneers in the therapeutic application of sea-bathing were Lettsom and Richard Russell, generally known as "Seawater Russell"

(1687-1759). In the early part of the eighteenth century Russell wrote two books on the efficacy of sea-bathing and sea-water drinking in the cure of various diseases, especially tuberculosis of glands, bone, joints, and skin. He claimed that his observations had shown that fishermen rarely had scrofulous diseases, and that their women had beautiful complexions, good teeth, and sound gums. The value of the associated sun-bathing seemed to have escaped him. Brighton owed much of its popularity to Russell. As time went on, the pleasures of sea-bathing caused its therapeutic effects to be overlooked. Lettsom, however, impressed by Russell's work, founded the Sea Bathing Infirmary, now known as the Royal Sea-bathing Hospital at Margate. Sir Henry pointed out that the Napoleonic wars gave a great impetus to the search for the cure for tuberculosis in France, and investigations ultimately led to the establishment of the first seaside institution at Berck, followed by numerous others. His own interest in and love of sea-bathing dated from childhood, and he attributed much of the good health he had enjoyed to long summer holidays spent on or in the sea. When he started the Cripples' Hospital at Alton, in 1908, he immediately practised sun treatment on the children under his care. And, later, when a marine beach was secured, sea-bathing was started as a therapeutic measure. The seaside branch at Hayling Island was ideal in situation and climate. The whole success of the treatment depended on the ability of the patient to respond to the strong stimuli supplied. Those who did not possess that ability were not exposed to these stimuli until their powers of response had been fortified and attuned. Cases likely to respond very satisfactorily were children of good constitution who, even if their local lesions caused anxiety, could react well. In his view children over the age of five years, with good digestion, who were doing well, were braced by exposure to cold air, and reacted well to natural stimuli, would almost always do better still at the seaside. Marine treatment offered the readiest means of beneficially influencing basal metabolism, which could be greatly increased. The quickened tissue change affected diseased as well as normal tissues, expediting healing processes. The sense of physical well-being, under the combined action of sun, sea air, and sea-water was very valuable as an aid to cure. Sir Henry outlined the procedure adopted with children during and after the bathe, and described the voracious appetites and the vivacity developed.

Dr. D. B. ROSENTHAL (Melbourne) opened a discussion on the

Incidence of Pleural Effusion in Artificial Pneumothorax

He said that the limitations of the application of artificial pneumothorax (A.P.) in the treatment of pulmonary tuberculosis depended on the stage of the disease, and on complications that might arise due in part at least to the treatment itself. Of these latter, the commonest and the most upsetting to both the patient and the physician was the development of a pleural effusion. The presence of fluid in a pneumothorax space might be attended by no untoward effects, but three undesirable sequelae were recognised. They were (1) great thickening of the pleura, (2) premature obliteration of the A.P. space by organisation of the fibrin in the fluid, and (3) the change of the fluid to pus. Dr. Rosenthal had attempted to assess the various aetiological factors

which might, either singly or together, have played a part in the development of fluid, and advanced the thesis that trauma to the pleura, in one way or the other, was the main provocative cause. Briefly reviewing the reported incidence of effusions, he pointed out that until reports were more carefully standardised, any accurate estimate was impossible. Some observers included small effusions in their figures, whilst others included only those large enough to cover the diaphragm or to require aspiration. The figures submitted by most authorities suggested that pleural effusions occurred in about 50 per cent., and tuberculous empyema in 5 to 10 per cent. of all cases of A.P. Of a series of 629 patients admitted to Gresswell Sanatorium in two years from April, 1933, to April, 1935, 595 were suffering from pulmonary tuberculosis, and 54 received A.P. therapy as part of their treatment. Of these 41 developed effusion—i.e., 76 per cent.; but if one excluded those in whom only a very small "puddle" of fluid formed, the number of effusions of clinical importance was 23—i.e., 43 per cent. of the total.

Each case had been carefully examined by fluoroscopy and by study of the radiogram for adhesions. The occurrence of a febrile reaction at the time of the appearance of each effusion was noted, in an attempt to assess the infective, as distinct from the traumatic, factor in the causation of effusion. These were not mutually exclusive; the presence of pyrexia at the time did not exclude trauma, to which it may have been secondary. It was interesting to note that adhesions of some degree were present in 46 out of the 54 cases. These ranged from fine strands to massive bands holding the lung to the chest-wall over a considerable area. In 4 cases no fluid and no adhesions were found; 4 had fluid and no adhesions; 9 had no fluid but adhesions; and 37 fluid and adhesions. Wide variation was noted—from 1 to 64 weeks—in the period elapsing between the establishment of A.P. and the appearance of fluid. Very small effusion, and those that became purulent—the least and the most important groups respectively—showed a tendency to earlier appearance than did the rest.

The present position of those in the series in whom A.P. was originally established was as follows: 30 were being continued; 7 were abandoned because adhesions prevented satisfactory collapse; 10 discontinued refills because of the presence of adhesions together with pleural effusion; and 7 discontinued refills because of the development of pyothorax. The only deaths in the series were 2 of the 7 cases of empyema.

The various aetiological factors were then considered in turn. Trauma to the pleura might arise from (1) repeated puncture; (2) introduction of a foreign body (including air) into the pleural space; (3) high intrapleural pressures; and (4) rupture of adhesions. Dr. Rosenthal discussed the various types of adhesions, and showed radiograms demonstrating cases of rupture of each type. Depending on the type of tissue involved, the results of rupture might cause a very small effusion, a larger serous effusion, or a purulent effusion. He mentioned that in intentional rupture of adhesions (Jacobaeus' operation) effusion occurred in about 50 per cent. of cases, and empyema in about 10 per cent. He thought that the number of cases of tuberculous infection of the pleura (unassociated with trauma) was small, a conclusion drawn from the mode of onset of the effusions, and from the comparison of the figures from the A.P. group with the "non A.P." group—43 per cent. and 7 per cent.

respectively. Acute exacerbation of disease in the contralateral lung had not been experienced following the appearance of fluid in the A.P. space. If indeed this was frequent, the development of fluid would in itself be an indication for reviewing the treatment. Climatic effect was considered to be of little moment. Recently Pisani and Smejkal had claimed that calcium gluconate was effective in preventing effusion in A.P., but he had been unable to confirm their results. In 16 of his cases of A.P. 8 received calcium and 8 served as controls, the cases being taken alternatively. Of the cases receiving calcium, 1 had no effusion, 5 had a small effusion, and 2 needed aspiration; of the 8 controls, 4 had no effusion, 3 had a small effusion, and 1 needed aspiration. In conclusion, he said that in his view small effusions were due to trauma only, whilst larger effusions were due to trauma plus infection; a relatively small proportion of effusions was due to a tuberculous pleurisy not associated with trauma. He advised conservative treatment, particularly avoidance of "compression" of the lung by use of positive intrapleural pressures. Partial collapse was always "selective," and the best results were obtained by adopting the technique of what had been aptly termed "hypotensive" pneumothorax. The word "compression" should be abandoned in favour of "collapse"; even better was Gravesen's conception of "relaxation" therapy. When air-replacement was practised it should be performed as infrequently as possible.

Dr. A. J. COLLINS (Sydney) said that effusions were not always proved to be tuberculous, even the guinea-pig test being negative. The nature of those effusions which were not aspirated was speculative. He agreed with Dr. Rosenthal that many who developed fluid had adhesions; but this did not necessarily associate the two. He preferred to think of the condition as being due to an extension of tuberculous disease to the pleura. The presence of adhesions certainly indicated past pleurisy. Trauma might cause contusion of the chest wall, and convert a dry pleurisy into a pleurisy with effusion. At the Royal Prince Alfred Hospital the incidence of effusions was about 54 per cent. He agreed that trauma played a very important part in their aetiology.

Dr. D'ARCY COWAN (Adelaide) preferred a dry A.P. He agreed that adhesions were usually present with effusions, and advised gradual alteration in intrapleural pressure, when this was desirable. He also suggested that re-expansion of the lung should be made a gradual process, as rapid expansion might cause effusion. He recommended the more general use of tuberculin in treatment, associated with A.P., but had had no success with calcium.

Dr. J. BELL FERGUSON (Melbourne) regarded effusion in A.P. as a common, worrying complication. He thought the determining factors were the presence of adhesions and high intrapleural pressures. He agreed with the treatment outlined by Dr. Rosenthal. When pus was present, he advocated the use of Metaphen, 1:3000 in olive oil.

Dr. B. ELWELL (Brisbane) spoke of the gravity of effusion complicating A.P. He advised the use of tuberculin with A.P.

Dr. A. WALKER (Sydney) found it difficult to believe that effusions were ever other than exudates. He thought that a large effusion was a somewhat sinister thing, and agreed with Dr. Rosenthal that aspiration should be as infrequent as possible.

Dr. H. WATSON (Melbourne) and Dr. W. J. NEWING (Melbourne) also spoke.

Dr. ROSENTHAL, in reply, desired to emphasise his conviction that most of these effusions were tuberculous, but were precipitated by trauma in some form; they were essentially a result of the nature of the treatment.

Treatment of Tuberculous Empyema

Dr. M. P. SUSMAN (Sydney) said that in discussing this subject it was necessary to lay stress on a commonplace—that we were dealing with a tuberculous patient and not just a local focus. Constitutional treatment was therefore essential throughout—including dietetic, hygienic, and medicinal measures. Each patient required individual treatment. Minor surgical procedures included aspiration, with or without air replacement and irrigation, and oleothorax. Major surgical operations consist of (1) intercostal drainage, open or closed; (2) thoracotomy and drainage; (3) phrenic avulsion, either alone or supplementing other procedures; (4) thoracoplasty, partial or complete; (5) rib resection and excision of granulation tissue and thickened pleura to bring close contact with visceral pleura.

The principles of treatment might be divided into general and special. General measures included (a) the avoidance of secondary infection or, if it occurred, its prompt and adequate treatment to minimise constitutional and local damage; and (b) the relief of symptoms, especially those due to mechanical causes, such as a large collection of fluid or a valvular pneumothorax. Special measures depended on two possibilities: (1) if the underlying lung was apparently healthy, the aim was to obliterate the empyema cavity by getting the lung to expand; (2) if the lung was diseased, and especially if there was cavitation, the pulmonary lesion had to be treated as well as the empyema, so that the aim was to keep the lung collapsed. It was thus clear that treatment was determined by the state of the lung or lungs, and the presence or absence of pyogenic infection. For the purpose of treatment cases could be considered under four groups: (1) no signs of pulmonary tuberculosis and no pyogenic organisms in the empyema; (2) pulmonary tuberculosis known to be present, but no pyogenic organisms in the empyema; (3) no signs of pulmonary tuberculosis, but pyogenic organisms present in the empyema; (4) pulmonary tuberculosis known to be present, and pyogenic organisms present in the empyema. The number of patients in groups 1 and 3 was much smaller than in groups 2 and 4. Dr. Susman detailed the appropriate treatment for each of the four groups describing illustrative cases. In group 1, he said that the important thing was to get the thoracoplasty done if it were necessary before secondary infection occurred. He discussed briefly pleural lavage, oleothorax, intercostal drainage, and thoracoplasty, and reviewed the results of treatment. He believed that the mortality of tuberculous empyema was between 30 and 50 per cent.

Dr. A. WALKER spoke of the gravity of tuberculous empyema. He thought conservative treatment was carried too far, and urged the adequate treatment of pleural effusions before they became frankly purulent. He urged the need for the physician in charge to keep an open mind in respect of treatment.

Dr. H. SEARBY (Melbourne) said that more co-operation between the surgical clinics and the sanatoria without operating facilities was desirable. He did not advise thoracoplasty in group 1 of Dr. Susman's classification. In group 2, if the lung tended to

re-expand whilst treatment was in progress, the condition was self-curative. Group 3 was difficult to treat satisfactorily. Rib resection appeared to give adequate drainage. He advised conservative treatment for months before thoracoplasty, but was pessimistic of the outcome.

Dr. L. DOYLE (Melbourne) thought that the essential factor was to bring the chest wall down to the lung: it was important to induce the correct mental outlook of the patient before surgical treatment was undertaken.

Dr. G. FOREMAN (Melbourne) discussed details of the technique of thoracoplasty. He thought that broncho-pleural fistula was commoner than the figures suggested.

Dr. BELL FERGUSON considered that the physician was sometimes too conservative in treating these cases.

Dr. A. PENNINGTON (Melbourne) referred to his experiences in the bacteriological investigations of these fluids, and Dr. D'ARCY COWAN suggested irrigation of the pleural space by saline as a preliminary measure.

Dr. ROSENTHAL agreed that lavage of the pleural space should be performed first with a bland fluid, such as saline, to which eusol could be added. He thought that oleothorax was frequently responsible for the failure of re-expansion later, and deprecated the use of oil in the presence of broncho-pleural fistula.

In reply, Dr. SUSMAN thought that open drainage was quite safe. If the lung would not expand, he advised early thoracoplasty in group 1. In group 2 there was more doubt. In answer to Dr. Doyle, he said that he considered local anaesthesia unsatisfactory for thoracoplasty.

(FROM OUR OWN CORRESPONDENT)

MEDICAL CURRICULUM AT EDINBURGH

At a meeting of the general council of Edinburgh University, Principal Sir Thomas Holland spoke of the reform of the curriculum as a matter of considerable public interest. The idea of expecting a man to be a general practitioner in science or engineering, had, he said, long been given up, but the average graduate in medicine—as in divinity—was still expected to be a safe general practitioner. At Edinburgh University a committee has been at work for some time planning reforms in the curriculum and many alterations in the methods of teaching have been made during the past few years. The teaching of physiology, for example, has been greatly changed. The various medical courses are being continually altered in an attempt to keep the school in tune with the changing and developing needs of both medical science and medical practice. An extra year added to the medical course would add 20 per cent. to the student's outlay for a medical degree, which was already expensive compared with that of other professions. A rash attempt to raise the standard to meet the demands of all the teachers would merely defeat the real object all had in view. In view of the limited accommodation in some of the laboratories and in the resources for clinical training at the Royal Infirmary, the university has been unable to accept more than one-half of the applicants who could show the basic educational standard required to undertake a medical training of university degree standard. The applications were now subject to scrutiny by a special committee, and preference was usually given

to those with the higher qualifications. During the session 1934-35, 180 men and 35 women started their medical course, while the total number of matriculated medical students was 1162 men and 166 women. The total number of matriculated students for all faculties was 3991.

The annual expenditure of the university shows little change from year to year. In 1934 it amounted to £294,264. In their report the finance committee reiterate the need of endowment of additional chairs, lectureships, laboratory equipment, library, fellowships, scholarships, and bursaries, and of funds for research and for general maintenance.

IRELAND

(FROM OUR OWN CORRESPONDENT)

THE IRISH HOSPITALS SWEEPSTAKE

THE draw of the sweepstake on the Cambridge-shire Race, being the sixteenth sweepstake held in aid of the Irish hospitals, took place last week. Despite gloomy prophecies the total receipts, and consequently the funds to accrue to the hospitals, showed an increase over the previous sweepstake held last June. The amount which will be handed to the National Hospital Trustees as a result of this sweepstake will be over £400,000. The total amount, from the sixteen sweepstakes from November, 1930, to June, 1935, collected for the hospitals was £8,367,002. In declaring the draw open Lord Powerscourt, chairman of the Associated Hospitals Committee, stated that the report of the Hospitals Commission containing recommendations for the disbursement of funds to the hospitals was now in the hands of the Minister for Local Government and Public Health, and it would soon be printed and made public. Until the Minister had time to study and approve the recommendations grants for the carrying out of extensive schemes could not be made. At present, however, the Minister was allowing grants to meet the deficits on the working of certain hospitals. The solution of the main problem, an adequate hospital scheme for the whole country, could not be undertaken until a large sum of money was in hand, and that was why no substantial grants were being made at present. Lord Powerscourt's clear statement should put an end to the suggestions made in certain quarters that the Government was holding up the money for some sinister purpose. The funds are in the hands of trustees, and any moneys not invested in trustee securities are on deposit in the Bank of Ireland.

ROYAL WORCESTER INFIRMARY: CONTRIBUTORY SCHEME.—This hospital has been overhauling the constitution of its contributory scheme in view of the fact that since the extended services of the hospital came into full operation there has been a deficit on the maintenance account of some £3000 per annum. The population served by the scheme is roughly 100,000, of whom about 22 per cent. are members, compared with an average of 28 per cent. in schemes throughout the country. The income thus raised is nearly £10,000 a year as compared with £14,000 a year from the average scheme of comparable size. It was recommended that new rates of contribution and a revised income limit scheme as recommended by the British Medical Association should be adopted whereby adult single members pay 3d. per week instead of 2d.; single persons with an income of more than £200 are excluded, but family men with an income of up to £300 a year are admitted. It is hoped that the changes will bring in another £2000 a year.

CORRESPONDENCE

ATTITUDE OF SURGERY TO HÆMATEMESIS

To the Editor of THE LANCET

SIR,—I have been much interested in studying Mr. Gordon-Taylor's address and his views of the place of surgery in the treatment of hæmatemesis from chronic peptic ulcer. My own views were expressed in a lecture published in *THE LANCET* of August 12th, 1933 (p. 335), but as this is over two years ago they must already be considered out of date. I do not wish to take any part in the statistical battle which is perennially fought out between the results of medical and surgical treatment. It is sufficient to say that my own experience shows that I have probably been fortunate (or, at any rate, that my patients have) for the result has nearly always justified my optimistic prognosis in these cases. But good fortune may not last and one must be prepared for the necessity to trim one's sails to a less favourable wind.

I should like, however, once more to stress two facts with which I hope that most of my colleagues, both medical and surgical, will agree. First, that serious hæmorrhage is a relatively rare complication of chronic peptic ulcer, especially in patients under forty. And, secondly, that acute ulcer is at least as common a cause of hæmorrhage (in my own experience a good deal commoner) as chronic ulcer. A further relevant fact, based on post-mortem study, is that acute ulceration may occur in the presence of chronic ulcer and, where this is the case, any hæmorrhage is as likely (I think more likely) to be due to the acute as to the chronic ulcer. Clinical experience can tell us nothing of the frequency of such hæmorrhages, and, although they have certainly caused death in some cases, they may be quite rare. But the possibility of an acute gastric ulcer causing a hæmorrhage in a patient who is known to have a chronic duodenal ulcer is not mentioned by Mr. Gordon-Taylor; yet it is a possibility which is worth bearing in mind and it has frequently deterred me from advising surgery in cases that have come within the indications which Mr. Gordon-Taylor has laid down.

Mr. Gordon-Taylor briefly mentions having operated on a few acute peptic ulcers but gives no details. Now I have been brought up to believe that the discovery of an acute ulcer at operation is always difficult and often impossible. Experience of autopsies on such cases would certainly support such a view. To me it seems fundamental that there should be no doubt whatever on this score and I should be grateful if Mr. Gordon-Taylor and other surgeons would give us their views on the possibilities of the surgical treatment of bleeding acute ulcers. If I am right in supposing that such a hæmorrhage is not very uncommon even in the presence of a chronic ulcer we can really not be quite certain of Mr. Gordon-Taylor's primary postulate (with which everyone will agree) that "almost the only pathological state which justifies urgent surgery is that of bleeding *from* (my italics) a chronic ulcer." And if surgery becomes more frequent as the result of Mr. Gordon-Taylor's skilful advocacy we may from time to time meet with the experience, not unfamiliar in an earlier age, of a "successful" operation failing to control the hæmorrhage.

In conclusion may I emphasise that I am seeking knowledge and that what I have written is not

intended to imply any criticism of, or fundamental disagreement with, Mr. Gordon-Taylor's extraordinarily able contribution to a problem which closely concerns the physician, the surgeon, and the general practitioner.

I am, Sir, yours faithfully,

London, W., Oct. 26th.

MAURICE E. SHAW.

To the Editor of THE LANCET

SIR,—I quite understand now that the peroration in Mr. Gordon-Taylor's article should be read in conjunction with the more moderate views expressed in the body of his paper, and that the flight of fancy went beyond his opinions and his practice. It is a dangerous latitude in an authoritative article and it is to be hoped that others will not take it literally.

I am sincerely sorry that my letter should have hurt Prof. Finsterer's many friends in this country. I can assure them that I did not intend to impute any lack of integrity when criticising his conclusions and statistics, and I trust that this will be understood. But his conclusions include such statements as "any hæmorrhage from an ulcer is almost as urgent as a perforation," and "operation for acute hæmorrhage gives the same good results as operation for non-bleeding ulcer," and one is entitled to regard critically the author of these sentences. Surely his friends who admire his technique would not follow him in these views. His statistics give 39 cases of severe hæmorrhage in which gastrectomy was performed within 48 hours with one death. There is no indication in his article that these cases were selected, and in view of his opinions quoted above one accepted them as being consecutive unselected cases of severe hæmorrhage. But I hear that Prof. Finsterer is a surgeon who is not attached to a hospital and his cases would have been selected previously by the general practitioners. Physicians may see in their practice a series of cases of severe hæmorrhage without a death, but they know that fatalities occur in their hospital wards. In referring to Prof. Finsterer's statistics the circumstances to which they apply should be made clear. If surgical technique can uniformly achieve these results in all cases of ulcer-hæmorrhage, why has it not done so? Then the problem would have ceased to exist.

The fatalities from ulcer-hæmorrhage are practically confined to a small group of cases. I believe that in recent years these cases have not been operated upon sufficiently often, or sufficiently early, but this must not be corrected by operating too widely. It is our duty now to attempt to recognise these cases and to recognise them as early as possible. It only partly solves the problem to wait for indications of the persistence of copious bleeding. Altogether it is clearly necessary that severe ulcer-hæmorrhage should be studied afresh.

I am, Sir, yours faithfully,

H. LETHEBY TIDY.

Devonshire-place, W., Oct. 28th.

PROTEIN SHOCK FOR UNDULANT FEVER

To the Editor of THE LANCET

SIR,—I have read with interest the notes of the case of undulant fever treated by protein shock, reported by Dr. Beaumont and Dr. Page in your last issue. The severity of the reaction produced by a T.A.B. vaccine injection intravenously is largely a question of dosage. In the series of cases of undulant

fever treated by protein shock therapy which I reported in THE LANCET of June 3rd, 1933 (p. 1177), the initial dose of the T.A.B. vaccine was generally 50 million organisms, though in special cases the dose was as low as 20 million. In none of these had I any serious upset.

Since then I have continued to use protein shock therapy regularly in cases of undulant fever coming under my care. In a series now of over twenty treated with varying doses of T.A.B. vaccine I have had no reactions of an alarming nature and the results have been consistently good. I feel confident that with due caution in dosage protein shock therapy can be used with great advantage in the routine treatment of cases of undulant fever without causing undue anxiety.

I am, Sir, yours faithfully,

SINCLAIR MILLER.

Harrogate Investigation Clinic, Oct. 28th.

A PECULIAR BODILY DISPROPORTION

To the Editor of THE LANCET

SIR,—Whilst I am not in a position to express an opinion comprising the general population in respect to the "peculiar bodily disproportion" about which Dr. Piney is solicitous, I can at any rate refer to the results of some 25 years' investigations of a special character which have some bearing on the subject. Together with their physiological capabilities, the anthropometry of athletes has engaged my attention and in the whole of my experience I have not seen a single example in whom the leg length was not more than 50 per cent. of the total body length. In the case of track athletes, the disproportion—to use Dr. Piney's term—is generally considerable; and even in the case of long-distance cyclists who have relatively short lower limbs the relation is still maintained.

So far I know of no example of a death under an anæsthetic having occurred in any one of this considerable number of young men with whom I have been acquainted; nor, although suicidal potentiality or mental instability cannot, I suppose, be excluded, have I heard of one example of felo de se or of admission to a lunatic asylum.

I am, Sir, yours faithfully,

Brook-street, W., Oct. 26th. ADOLPHE ABRAHAMS.

THE WAR MENTALITY

To the Editor of THE LANCET

SIR,—The appearance in your issue of Oct. 19th (p. 907) of the letter addressed to the statesmen of the world from the committee for war prophylaxis of the Netherlands Medical Association must have pleased a great many members of our profession. At the present time, when the international situation is fraught with such grave possibilities, it is the plain duty of each and every sane human being in the world to do his or her bit in the cause of peace.

As a profession we are pledged to the alleviation of suffering and the saving of life, and at a time when the whole trend of medical science is in the direction of preventive therapy, a situation has arisen which bids fair to threaten the lives of vast numbers of our species and the health of countless more. Surely this is a position in which the medical profession can and should take a strong stand. The education of the people is the surest way to peace, and here we are in a peculiarly privileged position in the face of that confident intimacy which exists between doctor and patient, extended as is

so often the case to the patient's relatives and friends. Here we have the opportunity for propaganda of the most useful type, in which we can do our share in bringing about an enlightenment of the people as a whole.

One would like to see some such body as the committee for war prophylaxis set up in this and in other countries, and one would like to see the churches and the schools combine with such bodies in a common effort to bring the peoples of the world as individuals and as groups to a sane outlook on international affairs and a resolute expurgation of the idea of war as an instrument of economic or of political negotiation.—I am, Sir, yours faithfully,

Ashwell, Herts, Oct. 23rd.

J. H. MOYNIHAN.

ASSOCIATION OF INDUSTRIAL MEDICAL OFFICERS

To the Editor of THE LANCET

SIR,—I shall be obliged if you will allow me to correct certain misconceptions that have arisen in connexion with the announcement sent to you, and published in your issue of Oct. 5th (p. 808), concerning the formation of the Association of Industrial Medical Officers. It was not intended to imply, nor was it stated, that this association replaces and continues the work of the advisory medical committee of the Industrial Welfare Society, for both bodies have sprung from the original membership of the pre-existing Council of Industrial Medicine. It was incorrect to state that the members of the association "continue to constitute" the advisory committee, for though many of the members of the former, including myself, have been members of the latter since its formation and continue to give their services to it, the advisory committee contains also a number of other medical practitioners whose interest in industrial medicine is of a more general or less active nature. The committee of the Industrial Welfare Society is largely an advisory body, whereas this association exists for mutual study and research, and its membership is limited to those actively engaged in industrial medicine. Close coöperation between the two bodies has been arranged.

I am, Sir, yours faithfully,

London, Oct. 24th. N. HOWARD MUMFERY,
Chairman, A.I.M.O.

GERMICIDAL PROPERTIES OF MERCURY PREPARATIONS

To the Editor of THE LANCET

SIR,—In your issue of Oct. 19th (p. 917) Drs. Reynolds and Stothart draw attention to a real weakness in the technique of determining germicidal efficiency. It so happens that this matter is the subject of a paper by us accepted on Sept. 3rd for publication in the next issue of the *Journal of Hygiene*. Therein we believe the true explanation is given, based on colloid-chemical considerations.

We are, Sir, yours faithfully,

London, Oct. 24th. JOHN GEORGE BAUMGARTNER,
MALCOLM DOUGLAS WALLACE.

TONBRIDGE COTTAGE HOSPITAL.—On Oct. 23rd Lady Camden opened the new Queen Victoria Cottage Hospital at Tonbridge. It consists of the buildings of a vacated isolation hospital which have been modernised. The estimated cost of the whole scheme is about £18,000, of which £5000 still has to be raised.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Prorogation and Dissolution

PARLIAMENT was prorogued by Royal Commission in the House of Lords on Oct. 25th until Nov. 19th, and the same night a Dissolution was announced by a Royal Proclamation issued as a supplement to the *London Gazette*. Thus came to an end the Parliament which was elected in October, 1931, with an enormous majority for the National Government. As announced by the Prime Minister (Mr. Baldwin) in the House of Commons on Oct. 23rd, the nomination of candidates in the forthcoming General Election will take place on Monday, Nov. 4th, and the poll on Thursday, Nov. 14th. The new Parliament will meet for the first time on Nov. 26th for the election of a Speaker and the swearing-in of Members. The State opening of Parliament will be on Dec. 3rd.

Dependent Children—Increased Allowances

In the House of Commons on Oct. 24th Mr. ERNEST BROWN, Minister of Labour, moved that the draft of the Unemployment Insurance (Increase of Benefit in respect of Dependent Children) Order laid before Parliament on Oct. 22nd be approved. The Statutory Committee, which was charged with looking after the destinies of the Insurance Fund under Part I. of the Act of 1934, had, he said, made to him a report. The report considered the condition of the fund. The fund was solvent, there was a certain reserve, and the committee, surveying the whole trend of events, had, after casting a mean of eight years in succession, come to the conclusion that, allowing for a certain figure of standard reserve, there was a disposable surplus of nearly £1,500,000. They recommended that the dependents' insurance benefit to children under Part I. of the Act should be raised from 2s. to 3s. This would affect on the average 240,000 households weekly and an average weekly number of children to the extent of 500,000. The committee had laid down a proviso that there should be an over-all limit of 41s. That limit was unique in the insurance system. The other point, which was perhaps just as important from the point of view of a consideration of policy, was that not only should there be this over-all limit, but there should be an actual figure expressed—namely, 41s. The effect of this would be twofold. At the moment there were a small number of households with very large families which got more than 41s. a week. Some drew as much as 46s., so that if the proviso had been accepted by the Government, if he had not put in an order disagreeing with the proviso, it would have meant an actual cut to a small number of large families of anything up to 5s. In the second place, if the "stop" was at 41s. there would not be the full allowance to the larger families. The 41s. level was struck at a family consisting of five children or more. He had figures showing how the scale would work out in the case of families of more than five without the proviso. This would be the new rate as compared with the old: man and wife and one dependent child, old rate 28s., new 29s.; man and wife and two dependent children, old rate 30s., new rate 32s.; man and wife and three dependent children, old rate 32s., new rate 35s.; man and wife and four dependent children, old rate 34s., new rate 38s.; man and wife and five dependent children, old rate 36s., new 41s.; man and wife and six dependent children, old rate 38s., new 44s.; man and wife and seven dependent children, old rate 40s., new rate 50s.; man and wife and nine dependent children, old rate 44s., new rate 53s.; man and wife and ten dependent children, old rate 46s., new rate 56s. It was estimated that the families under the scheme above the five children level numbered some 10,000 and that above eight there were some 1000 families. The committee in their report did not

urge the principle of the over-all limit on financial grounds. The 10,000 families with over five children and the 1000 with eight children would make no substantial difference to the financial arrangements. The committee urged it on very grave grounds of public policy. The Government had disagreed with the proviso without in any way deciding for or against the general issue which the committee raised. They had come to the conclusion that that issue, as an issue, should be left open for further consideration, and they had therefore decided not to accept the committee's recommendation that there should be a limit of 41s. on the amount of benefit paid in any individual case. He proposed that the new scale should take effect from Oct. 31st, and the first payments would be made on Nov. 7th and 8th. The motion approving the order was agreed to.

Departmental Committee on Workmen's Compensation

In the House of Commons on Oct. 24th Mr. GEOFFREY PETO asked the Home Secretary the names of the committee on the operation of the Workmen's Compensation Act in relation to the settlement of claims by the payment of lump sums, the position of medical referees, miners' nystagmus, and other matters. In reply Captain WALLACE gave the following list of the names of the committee and the terms of reference:—His Honour Judge Stewart (Chairman); Mr. H. E. Allen (Secretary of the North Wales Coalowners' Association); Mr. R. R. Bannatyne, C.B. (Assistant Under-Secretary of State, Home Office); Dr. J. C. Bridge, C.B.E. (Senior Medical Inspector of Factories); Dr. J. Gilmour (Regional Medical Officer, Department of Health for Scotland); Mr. F. Holroyd, J.P. (Senior Vice-President, National Confederation of Employers' Organisations); Mr. Joseph Jones, C.B.E., J.P. (President, Mine Workers' Federation); Mr. W. Kean, J.P. (General Secretary, National Union of Gold, Silver, and Allied Trades); and Sir Walter Kinnear K.B.E. (Controller, National Health Insurance Department, Ministry of Health). The terms of reference were given as follows:—"To inquire into the arrangements at present in operation with a view to the restoration of the working capacity of persons injured by accidents, and to report as to what improvements or developments are desirable, and what steps are expedient to give effect thereto regard being had to the recommendations made in the report issued by the British Medical Association in February, 1935, on 'Fractures'."

HOUSE OF COMMONS

WEDNESDAY, OCT. 23RD

Ex-Service Men and Hospital Treatment

Sir P. HARRIS asked the Minister of Pensions whether it would require legislation in order to give the promised concession to ex-Service men entering hospitals, or whether it could be carried out by administrative action, and, if so, from what date would such action become operative.—Major G. F. DAVIES, Lord of the Treasury, replied: No legislation will be necessary. The concession will take effect as soon as the necessary instructions can be got out, which should be within the next ten days.

THURSDAY, OCT. 24TH

National Health Insurance and Maternity Benefit

Mr. BUCHANAN asked the Minister of Health if he was aware that great hardships had been caused among numbers of households where the father had been out of work for some time and he had not a certain insurance record, and, as a result, had lost his title to maternity benefit; and if he would take steps to have this benefit granted to all, despite the period of unemployment.—Sir KINGSLEY WOOD replied: I am aware that cases have arisen in which title to maternity benefit has been lost by reason of prolonged unemployment, but the hon. Member will recall that in the National Health Insurance

and Contributory Pensions Act of the present session provision was made under which the title to maternity benefit will no longer cease with the expiration of the free insurance period but will be retained so long as insurance is continued on proof of prolonged unemployment. Further, the provision in the Act under which arrears due to unemployment are in future to be completely excused will prevent any reduction of maternity benefit by reason of unemployment.

Electric Welding and Health of Workers

Miss WARD asked the Home Secretary whether, in view of the use of electric welding as an industrial process, consideration had been given to the question of the effect on the health of the workers so engaged.—Captain WALLACE, Under-Secretary, Home Office, replied: Certainly, and steps have been taken with a view to preventing injury to health. I may refer in this connexion to Number 18 of the Shipbuilding Regulations under the Factory Acts, requiring adequate ventilation, and to the Factory Department Memorandum (Form 329) on Electric Arc Welding.

Spahlinger Bovine Vaccine

Mr. PETHERICK asked the Minister of Agriculture if he had received a report on the tests of the Spahlinger treatment of tuberculous cattle carried out by His Majesty's Government in Northern Ireland, and if he could make a statement regarding his intentions in relation thereto.—Major DAVIES replied: My right hon. friend has read the report with much interest. It is now being examined by the Committee on Tuberculosis appointed jointly by the Medical Research Council and the Agricultural Research Council. The views of the committee in detail will not be available for some days, but it is understood that they will probably recommend that, arising out of the report, further investigations should be undertaken in Great Britain. Any such recommendations will be promptly and sympathetically considered by my right hon. friend.

Drunkenness Statistics

Mr. ISAAC FOOT asked the Home Secretary the number of proceedings and convictions for drunkenness in England and Wales during the calendar year 1934.—Sir JOHN SIMON replied: The figures of proceedings and of convictions for drunkenness in England and Wales during 1934 were, respectively, 46,293 and 39,748.

Pensioners and Health Insurance

Sir MERVYN MANNINGHAM-BULLER asked the Minister of Pensions if he was aware that pensioners, in some instances, through ignorance or neglect, failed to maintain or make certain of their position in health insurance and so lose or endangered their title to benefit and contributory pension; and whether he would take steps to enable them to ascertain or establish their rights.—Mr. R. S. HUDSON replied: Yes, Sir. Cases of the kind referred to have come to my notice. I am glad to say that with the co-operation of my right hon. friend the Minister of Health special arrangements have now been made to meet them as far as possible. For this purpose pensioners who are in any doubt as to their position in health insurance will be invited to communicate full particulars of their cases to the chief area officers of my department by whom they will be placed before the Ministry of Health. Special notices are being sent out, and in addition instructions will be given to each pensioner in his pension book.

Pensioners and Hospital Treatment

Sir MERVYN MANNINGHAM-BULLER asked the Minister of Pensions whether he was aware that many pensioners who had lost regular work through having to undergo treatment for their war disabilities in hospital were anxious to know, after a long stay in hospital, if they would be able on discharge to regain employment; and whether he could arrange with the Ministry of Labour to assist them to regain employment.—Mr. R. S. HUDSON replied: Yes, Sir; and I am glad to say that with the help of my right hon. friend the Minister of Labour, arrangements have been made whereby on receipt of a form of registration from a patient who is about to be discharged from hospital, the employment exchange nearest to his home will take all possible steps to secure

his prompt return to employment, either with his former employer or otherwise. I may add that I have issued a circular (copies of which have been placed in the library) to all war pensions committees throughout the country calling for special attention to the points raised in this and the last question, and inviting their active co-operation.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Vice-Admiral Sir Reginald Bond has been awarded a Good Service pension of £100 a year, from Sept. 23rd. in the vacancy created by the death of Surg. Vice-Admiral Sir Joseph Chambers.

Surg. Lt.-Comdr. T. F. Crean to *Pembroke* for R.M. Infirmary, Deal; E. R. Sorley to *Pembroke* for R.N.B.; and J. G. Currie to *Ganges* for R.N. Sick Quarters, Shotley.

Surg. Lt.-Comdr. (D) T. Hunt to *Victory* for R.N. Hosp., Haslar.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. K. W. Martin to *Victory* for R.N. Hosp., Haslar.

Proby. Surg. Lt. W. J. Heely to *Curacao*.

Proby. Surg. Sub-Lt. R. F. Hand to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS

Capt. N. H. Lindsay is placed on the half-pay list on account of ill-health.

Short Serv. Commissions: Lts. (on prob.) L. C. Card and H. C. George are confirmed in their rank.

REGULAR ARMY RESERVE OF OFFICERS

Col. L. M. Purser, D.S.O. (late R.A.M.C.), and Lt.-Col. G. S. Parkinson, D.S.O., having attained the age limit of liability to recall, cease to belong to the Res. of Officers.

SUPPLEMENTARY RESERVE OF OFFICERS

H. D. K. Wright to be Lt.

TERRITORIAL ARMY

Maj. C. Russell, M.C., M.B., R.A.M.C., to be Divl. Adjnt., 54th (E. Anglian) Div., vice Maj. W. Shakespeare, vacated.

Capt. R. G. Addenbrooke and R. E. Holme to be Maj. s.

Capt. A. G. Bryce, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

T. H. Dockrell to be Lt.

ROYAL AIR FORCE

Squadron Leaders H. McW. Daniel to No. 3 Flying Training School, Grantham, for duty as Medical Officer, and E. N. H. Gray to No. 5 Flying Training School, Sealand, for duty as Medical Officer.

R. A. Cumming is granted a short service commission as a Flying Officer for three years on the active list.

INDIAN MEDICAL SERVICE

Lt.-Col. A. J. H. Russell, C.B.E., M.D., I.M.S., Honorary Surgeon to the Viceroy of India, has been appointed Honorary Surgeon to the King, with promotion to the rank of brevet colonel, in succession to Col. C. A. Gill, I.M.S., who has retired.

The official notification of Oct. 18th, 1929, regarding the retirement of Capt. (now Maj.) J. C. Drummond is cancelled.

Indian Medical Department.—Capt. (Sen. Assist. Surg.) G. F. Duckworth retires, on account of ill-health.

DEATHS IN THE SERVICES

Lt.-Col. RALPH HENRY MADDOX, C.I.E., I.M.S. (ret'd.), who died on Oct. 18th at Hove, aged 71 years, was son of Rev. R. H. Maddox, rector of Kirkheaton, Yorks. He was educated at Haileybury and Edinburgh, where he qualified in 1887. He entered the Indian Medical Service five years later, served with the Waziristan Expedition, gained the Egyptian medal at Dongola, and was present at the capture of the Sempahga Pass. In 1899 he was appointed deputy sanitary commissioner of Bengal, and later superintendent of jails. He was transferred to Bihar and Orissa in 1912, took part in the European war from 1916-18, and was created C.I.E. in 1919. He occupied the post of inspector-general of civil hospitals in 1921, and retired in 1922. He married Lucy Lillian, daughter of Mr. Walter Wheeler of Belfast.

PANEL AND CONTRACT PRACTICE

London Insurance Committee and its Personnel

At its annual meeting on Oct. 24th the London Insurance Committee appointed Dr. E. A. Gregg as its chairman for the ensuing year. This is the first time for an insurance practitioner to hold this office; the only previous medical chairman (1929-30) was Mr. T. B. Layton, the otologist. The meeting was attended by the Minister of Health, who is the senior surviving ex-chairman. Sir Kingsley Wood was accompanied by Sir George Chrystal, the new permanent secretary of the Ministry, and by Mr. H. A. de Montmorency, an assistant secretary; and but for an urgent engagement elsewhere Sir Edward Campbell, Parliamentary private secretary to the Minister, who is also a former member of the committee, would have been present. Sir Kingsley, in a happy address, contrasted the position to-day with that when he was chairman eighteen years ago. The increase in the cost of drugs he attributed partly to the increase in the insured population, partly to the development of new and expensive forms of treatment. The cost per head in England was some 58 per cent. above that in Scotland; England was, he feared, in danger of becoming a nation of confirmed medicine drinkers; he would prefer to see people drinking more milk and less medicine.

An Employer's Complaint

"We cannot complete this report without saying that the employer's communications were characterised by an amount of prejudice and lack of balance which is happily rare in these cases, and were not free from a certain disingenuousness. He was impatient of any kind of impartial or judicial investigation into the practitioner's conduct, and when afforded an opportunity of attending the hearing peremptorily refused to do so."

So runs the last paragraph of a report of the medical service subcommittee upon a case in which a practitioner was cautioned as to the need for greater care in future and, with her partner, is to be called upon to rearrange her surgery hours to the satisfaction of the committee.

An insured person, who had been ill for about a week but had not seen her doctor, called with a friend at Dr. A's surgery early on a Thursday evening, when Dr. A had no surgery hour. Dr. A was out, but her partner (Dr. B) was seeing patients

in the surgery by appointment. The two girls spoke to Dr. B, who was seeing another patient out, and inquired whether the doctor could see them, but she told them she was seeing patients only by appointment that evening, and the patient construed this as an indication that the doctor would not provide her with treatment. Dr. B was hurrying to finish her surgery work in order that she might attend an urgent call, and while it was made clear to her that the applicant was an insurance patient she did not appreciate that the girl was in need of urgent attention and did not question the patient as to her condition. The patient and her friend said they mentioned the existence of a mammary abscess, but the doctor could not remember hearing any reference to it. The friend suggested their applying to a hospital for treatment and in this suggestion Dr. B, unwisely as it turned out, acquiesced. The patient was admitted to hospital and operated upon the same evening.

Thus there were extenuating circumstances in a case which when raised by the employer looked a very bad one. On the one hand a doctor anxious to get away to an urgent case; on the other a patient who failed to impress upon the doctor that she needed immediate treatment, although she was in pain. The subcommittee pointed out that they had always taken the view that while it is the duty of an insured person to indicate, where possible, whether treatment is required urgently there is also an onus upon the doctor to elicit as much information as possible in order to decide whether treatment is urgently necessary. They thought that Dr. B committed an error of judgment in dealing with the case as she did, and that as a result there was a failure to provide treatment for an insured patient, and consequently that Dr. A had failed, as the result of the action of her partner, to comply with the terms of service. The subcommittee added, however, that while they had no alternative on the facts but to find that there was a failure to provide treatment, they were satisfied by the frank and sympathetic bearing of Dr. B that this was an isolated error of judgment attributable to her anxiety to visit another case which she knew to be urgent.

But what a lot of trouble might have been saved if the girl had sought medical advice earlier instead of waiting until surgical interference was urgently necessary.

PUBLIC HEALTH

Vital Statistics of 1934

In his Statistical Review of England and Wales for 1934¹ the Registrar-General has to tabulate nearly half a million deaths and some 600,000 births, and to produce from this prodigious mass of material tables which provide for the wants of both national and local authorities, as well as for the exacting needs of the medical statistician and of social workers. From this task he emerges, as usual, triumphant, condensing a wealth of detail into what is—considering the material set out—an astonishingly small space. In the current volume a minor but valuable innovation has been introduced. In previous issues Table 17 has included the crude death-rate for each administrative area of the country—county, county borough, urban and rural district. In view of the

well-known fallacies involved in the comparison of crude rates, these particulars are insufficient to allow the local patriot to compare the mortality experience of his own area with that of other areas. To this table the Registrar-General has now added a standardising factor for each area (or comparability factor, as he terms it) so that by a simple multiplication of the crude rate by this factor the standardised death-rate is reached, and differences in the age-constitution of the populations thus overcome. This addition should prove of considerable service. On the whole, the national figures for 1934 are very favourable. The standardised death-rate from all causes was 10.4 per 1000 for males and 8.3 for females, rates which are both below any that have been previously recorded. Comparison of 1934 with the experience of 1921-30 shows that this advantage of the former year lay mainly in its first quarter, to which the relative absence of influenza must have

¹New Annual Series, No. 14. Tables. Part I.: Medical. 1935. 6s. net.

largely contributed. Of the last dozen years only 1930 has had an equally low death-rate from this cause. Other respiratory causes—bronchitis and broncho-pneumonia—were also somewhat low, while respiratory tuberculosis continued its decline and, in fact, touched another low record—586 deaths per million compared with a level of 721 in 1926–30 and 1208 in 1901–05. Infant mortality also fell below any previously recorded level and for the first time entered the “fifties,” the rate being 59 deaths per 1000 live births. That substantial improvement is still possible is suggested by the differences that may be observed between various parts of the country. In 1934 the rate varied from 49 per 1000 in the east and south-west to 66 in the north and 64 in Wales; from 53 in the rural districts to 66 in the county boroughs and 67 in London administrative county. Rather more than half the infant mortality in the country as a whole fell, in 1934, in the first four weeks of life, but even at this period considerable geographical variations exist, the rate for London being peculiarly low. Examination of the death-rates at ages shows that the favourable position of 1934 compared with the last quinquennium, 1926–30, extended to every age-group with the single exception of the years 5–10 at which the rate was unchanged. The absence of decline at these ages is no doubt due in part to the prevalence of scarlet fever and diphtheria in the current year. The death-rate from the former at ages under fifteen was 83 per million as compared with 55 in 1926–30 (both, of course, trifling compared with the figure of 366 in 1901–05 and 2018 in 1871–75); the death-rate from diphtheria in childhood was higher than in any year since 1921, being 402 per million under fifteen years of age compared with 306 in 1921–30. Of other epidemic diseases measles produced a normal, and whooping-cough a rather below normal, death-rate, while the epidemic of cerebro-spinal fever which reached its peak in 1931 continued its somewhat slow decline. From typhoid fever a small residue of deaths still remains—159, or 4 per million inhabitants, in 1934 compared with a rate of 13 ten years ago. The standardised death-rate from cancer has shown no significant change since 1925.

Out-patients at L.C.C. Hospitals

Ever since the large poor-law hospitals in London were appropriated by the London County Council certain groups of cases have been attending for out-patient examination and treatment. In general these attendances have been limited to emergencies, the after-care of in-patients, persons entitled to outdoor medical relief, and women attending maternity clinics. For reasons which it is not difficult to divine it has not proved possible to confine out-patient treatment strictly to these classes. Certain poor-law hospitals had already been doing rather more, and the growing reputation of the L.C.C. hospitals since the transfer has led to an increasing resort to them for ambulatory treatment. It is now proposed to extend this treatment to other groups. A patient sent by his own medical attendant for consultation or special examination (X rays, laboratory investigation) will be accepted on an almoner's report that he is unable to obtain for himself the special advice or investigation required. A patient, whether applying on his own or his doctor's initiative, may receive immediate treatment, but shall continue to attend only if the hospital is satisfied that he cannot be adequately treated by his own doctor (or by a district medical officer if he has no doctor of his own)

and if the almoner is satisfied that he cannot obtain for himself the required treatment. Should these conditions not be fulfilled the patient is to be referred to his own doctor or to the district medical officer. The appointment of almoners to L.C.C. hospitals has made it possible to ensure that this information is available. The new policy has the approval of the voluntary hospitals committee for London.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 19TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2969; diphtheria, 1237; enteric fever, 29; acute pneumonia (primary or influenzal), 646; puerperal fever, 41; puerperal pyrexia, 116; cerebro-spinal fever, 14; acute poliomyelitis, 23; acute polio-encephalitis, 2; encephalitis lethargica, 5; dysentery, 23; ophthalmia neonatorum, 90. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Oct. 25th was 3052, *v.* fever, 1089; diphtheria, 1197; measles 263; puerperal fever, 16 mothers (plus lethargica, 266; poliomyelitis, 16. At there were 22 babies (plus 11 mot) neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox or enteric fever, 13 (0) from measles, 4 (0) from scarlet fever, 11 (2) from whooping-cough, 25 (3) from diphtheria, 51 (15) from diarrhoea and enteritis under two years, and 24 (3) from influenza. The figures in parentheses are those for London itself.

Measles proved fatal in 5 cases at Manchester, 4 at Middlesbrough, and 2 at Bootle. Liverpool reported 3 deaths from diphtheria; Portsmouth, Salford, Birmingham, and Worcester each 2. Liverpool had 8 fatal cases of enteritis, St. Helens 3, no other great town more than 2.

The number of stillbirths notified during the week was 237 (corresponding to a rate of 36 per 1000 total births), including 48 in London.

OBITUARY

IAN DISHART SUTTIE, M.D., F.R.F.P.S. Glasg.

Dr. Suttie, whose death last week came as a blow to his friends, was well known in London for his work at the Institute of Medical Psychology, where he and his wife had both been on the staff for many years. Son of Dr. William Suttie, an Edinburgh graduate practising in Glasgow, he was born there in 1889, studied at the university, and took his medical degree in 1914. Then for five years he was on war service in France, India, and Mesopotamia, on his return joining the staff of the Glasgow Royal Asylum at Gartnavel where he met Dr. Jane Isabel Robertson who became his wife. For a time he was medical superintendent to the criminal asylum at Perth, an appointment which he gave up when he came south to join the Tavistock Clinic, as it then was. Dr. Suttie described himself as a sociologist and his writings, which appeared mostly in mental and neurological journals, dealt with such subjects as the significance of the sexual instinct, the psychopathic inheritance, the herd instinct, and mental recapitulation. His last book,¹ which has only just appeared, is a critical study of the Freudian psychology in its social application. In his preface to this book Dr. J. A. Hadfield remarks on the

¹ The Origins of Love and Hate. London: Kegan Paul, Trench, Trubner and Co., Ltd. Pp. 275. 10s. 6d.

objective basis of the work recorded, which is its distinctive feature. The starting point of Dr. Suttie's conception of human life and development is the need for companionship, and upon this need he founds his conception of love and his insistence upon this factor as against the Freudian theory of sex; his views of religion are matriarchal in contrast to the patriarchal view of Freud. The book correlates the author's life study of psychology, sociology, and anthropology.

CHARLES FREDERICK RUMBOLL, M.D. Durh.

Dr. Rumboll, who died at Melksham, Wilts, on Oct. 23rd, was born at Calne in 1859, the son of

Charles L. Rumboll of Bedford. Educated at Epsom College, he entered St. Bartholomew's Hospital from which he qualified in 1882. He then took medical degrees at Durham University and in 1886 qualified for the gold medal in the M.D. He was in practice at Melksham for over 40 years and was surgeon to the cottage hospital and local friendly societies. Having become a barrister-at-law of the Inner Temple, he was appointed to the commission of peace and later deputy lieutenant for the county. For many years he served in the 2nd Wilts Volunteers, retiring with the rank of lieutenant-colonel. Dr. Rumboll married Edith, daughter of W. H. Cross, J.P. for Middlesex, who survives him without issue.

MEDICAL NEWS

University of Oxford

Dr. John Mellanby, professor of physiology in the University of London, at St. Thomas's Hospital, has been appointed to the Waynflete chair of physiology in the University of Oxford.

Born at West Hartlepool in 1878, Prof. Mellanby is the younger brother of Prof. Alexander Mellanby of Glasgow, and the elder brother of Prof. Edward Mellanby, F.R.S., secretary of the Medical Research Council. He was educated at Barnard Castle School, Emmanuel College, Cambridge, and the Manchester Royal Infirmary. After leaving Cambridge in 1902 he worked at the Wellcome Research Laboratories at Herne Hill. There he started the physiological laboratory, and for two years carried out investigations on biological methods of standardisation and the isolation of diphtheria toxin and antitoxin. He qualified in 1906, gaining the Raymond Horton-Smith prize for his M.D. thesis at Cambridge in 1907. After qualification he held the George Henry Lewes studentship at Cambridge, and devoted himself to physiological research on the coagulation of blood. He was appointed head of the department of physiology at St. Thomas's Hospital medical school in 1909, and was given the title of professor by London University in 1920. In 1929 he was elected a fellow of the Royal Society in recognition especially of his studies on the coagulation of blood and the mechanism of pancreatic secretion. He was editor of *Physiological Abstracts* from 1925 to 1935, and has acted as examiner at the Universities of Cambridge, Oxford, Leeds, and Sheffield, and for the diplomas of the Royal College of Surgeons.

University of Cambridge

Dr. Thomas Shirley Hele, lecturer in biochemistry in the University, has been elected master of Emmanuel College.

An entrance scholarship has been founded at Peterhouse which is restricted to candidates who intend to study medicine. It may be awarded for proficiency in mathematics, classics, natural sciences, or history. Further particulars will be found in our advertisement columns.

Society of Apothecaries of London

At recent examinations the following candidates were successful:—

Surgery.—C. N. Chowdary, Univ. of Durh.; P. D. Lynch, Guy's Hosp.; W. J. Pinto, Univ. of Madras; M. Q. H. Siddiki, Univ. of Leeds; and G. W. van Mentz and G. M. Williams, London Hosp.

Medicine.—R. H. Bembridge, King's Coll. Hosp., and A. Morgan, Univ. of Manch.

Forensic Medicine.—R. H. Bembridge, King's Coll. Hosp.; E. R. Jones, St. Mary's Hosp.; A. Morgan, Univ. of Manch.; and G. M. Williams, London Hosp.

Midwifery.—H. Burrows, Univ. of Manch.; E. M. Craggs, Middlesex Hosp.; F. J. H. D. de Marigny, Guy's Hosp.; M. G. H. Jones and J. R. Roeyn-Jones, Welsh National School of Medicine; M. Q. H. Siddiki, Univ. of Leeds; H. L. W. Sixsmith, Welsh National School of Medicine; R. L. Wahmsley, Univs. of Camb. and Leeds; and C. W. Williams, Welsh National School of Medicine.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery: C. N. Chowdary, E. M. Craggs, A. Morgan, and W. J. Pinto.

Lectures for School Medical Officers

Two lectures for school medical officers on the diagnosis of congenital syphilis will be given by Dr. David Nabarro at the Hospital for Sick Children, Great Ormond-street, London, W.C., on Monday and Tuesday, Nov. 18th and 19th, at 2.30 p.m.

Royal College of Physicians of London

A Leverhulme scholarship of the annual value of £500 will shortly be awarded by the College. The scholar must undertake the investigation of some problem of disease in any branch of medicine. Further information will be found in our advertisement columns.

University of London

The title of emeritus professor of bacteriology in the University has been conferred on Dr. J. W. H. Eyre, formerly professor of bacteriology at Guy's Hospital medical school. Dr. Alexander Haddow has been reappointed Laura de Saliceto student.

University of Reading

At a congregation to be held on Dec. 2nd, when Sir Austen Chamberlain will be installed as Chancellor, the honorary degree of D.Sc. will be conferred on Sir Gowland Hopkins, O.M., P.R.S. Other recipients of honorary degrees will include Monsieur Herriot, Sir Robert Vansittart, Lord Rutherford, O.M., and Sir Joseph J. Thomson, O.M.

Scottish Conjoint Board

At recent examinations of the conjoint board of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow the following candidates were successful:—

L.R.C.P., L.R.C.S., AND L.R.F.P. & S.

M. R. Schleifer, S. H. Harrison, M. B. Spiegel, I. J. G. Morat, Joseph Freeman, Harry Farber, Louis Schmullian, Johannes Hart, M. W. U. Alwi, John Orr, S. J. Lederman, George Boyd, T. R. Murphy, Ruth Schurer, C. S. Parker, Hugh Henderson, H. T. Rachlin, D. H. Abbott, Marta Adolfsson, Louis Landman, David Simon, M. S. Hendriks, R. O. Walker, P. S. Gorla, G. B. Shirlaw, Sarah L. Mulholland, Otto Moses, Willi Straus, C. J. Greenberg, A. E. Thompson, W. F. M. Unger, F. P. Perera, O. W. Nardesio, D. S. Abeyagunawardene, John Jamieson, Abraham Berkow, Thomas Miller, J. E. Heller, Herbert Levy, Karl Melzer, Ralph Coff, H. G. Garas, Frances Hunter, Sanmugan Rajendram, Beate Isserlin, Solomon Maranov, Ferenc Kellermann, and M. J. Philip.

Tuberculosis Association

A meeting of this association will be held at Manson House, 26, Portland-place, London, W., on Friday, Nov. 22nd, at 5.15 p.m., at which Sir St. Clair Thomson will speak on tuberculosis of the upper respiratory tract, and Mr. H. B. Bickerton on tuberculosis of the eye. The meeting will be resumed at 8.30 p.m., when Dr. E. L. Middleton and Dr. P. Hefernan will discuss industrialism and tuberculosis.

Society of Chemical Industry

A joint meeting of the London section and the food group of this society will be held in the rooms of the Chemical Society at Burlington House, Piccadilly, London, W., on Monday, Nov. 4th, at 8 p.m., when Prof. I. M. Heilbron, F.R.S., will deliver a Jubilee memorial lecture entitled *Chemical Elixirs of Life*. He will deal with recent developments in the chemistry of the sterols and related compounds.

National University of Ireland

A travelling studentship in physiology has been awarded to Dr. D. K. O'Donovan, University College, Dublin.

Ministry of Health

Mr. S. F. Wilkinson has been appointed assistant private secretary to Sir Kingsley Wood; Mr. T. W. Williams private secretary to Mr. Shakespeare; and Mr. J. E. Pater private secretary to Dr. MacNalty.

Scholarships for Sons of Medical Men

Two £100 scholarships are again being offered at Port Regis preparatory school to sons of medical men. The examination is being held in March, 1936, and candidates must be under nine years of age at the time of competing. Applications should be addressed to the headmaster, Port Regis, Broadstairs, not later than Feb. 20th.

War Relief in Abyssinia

The British Red Cross Society has received £5000 from Lady Ogle towards the organisation and dispatch of relief to the Ethiopian war zone. The total now in hand is some £19,000, and a small advance ambulance unit will leave London for Abyssinia about Nov. 17th. Further funds are urgently required for the maintenance and enlargement of this unit, and may be sent to Sir Arthur Stanley, British Red Cross Society, 14, Grosvenor-crescent, S.W.1.

Children's Play Clinic at Guy's Hospital

In connexion with the department of medical psychology at this hospital a children's play clinic has been started. Toys are needed for the new venture.

Alford Memorial Cottage Hospital

Sir Lancelot Travers opened a new ward, new quarters for nurses, and an X ray department at this hospital on Oct. 18th. The extensions have cost over £2000, of which £1000 has yet to be raised.

Plymouth City Hospital

The foundation-stone of a new nurses' home for this hospital was laid on Oct. 16th. It is to be a three-storied building and will provide accommodation for 152 nurses. There will be a recreation-room, a library, a dance hall, and a laundry.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

TUESDAY.—3.30 P.M., Dr. Carmichael: The Sympathetic Nervous System (II.).

WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.

THURSDAY.—3.30 P.M., Dr. Carmichael: The Sympathetic Nervous System (III.).

FRIDAY.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (V.).

Out-patient clinic daily at 2 P.M.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 7th.—2 P.M., Dr. B. Shires: Treatment of Nervi with Radium. 3 P.M., Dr. W. W. Payne: Diabetes (II.), Treatment.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Nov. 6th.—4.30 P.M., Mr. Kenneth Walker: The Treatment of Malignant Disease of the Genito-urinary Tract.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL, N.W.

WEDNESDAY, Nov. 6th.—4 P.M., Dr. H. V. Morlock: Diagnosis and Treatment of Intrathoracic New Growths.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Nov. 6th.—4 P.M. (St. James' Hospital, Ouseley-road, S.W.), Dr. C. E. Lakin: Demonstration of medical cases.

objective basis of the work recorded, which is its distinctive feature. The starting point of Dr. Suttie's conception of human life and development is the need for companionship, and upon this need he founds his conception of love and his insistence upon this factor as against the Freudian theory of sex; his views of religion are matriarchal in contrast to the patriarchal view of Freud. The book correlates the author's life study of psychology, sociology, and anthropology.

CHARLES FREDERICK RUMBOLL, M.D. Durh.

Dr. Rumboll, who died at Melksham, Wilts, on Oct. 23rd, was born at Calne in 1859, the son of

Charles L. Rumboll of Bedford. Educated at Epsom College, he entered St. Bartholomew's Hospital from which he qualified in 1882. He then took medical degrees at Durham University and in 1886 qualified for the gold medal in the M.D. He was in practice at Melksham for over 40 years and was surgeon to the cottage hospital and local friendly societies. Having become a barrister-at-law of the Inner Temple, he was appointed to the commission of peace and later deputy lieutenant for the county. For many years he served in the 2nd Wilts Volunteers, retiring with the rank of lieutenant-colonel. Dr. Rumboll married Edith, daughter of W. H. Cross, J.P. for Middlesex, who survives him without issue.

MEDICAL NEWS

University of Oxford

Dr. John Mellanby, professor of physiology in the University of London, at St. Thomas's Hospital, has been appointed to the Waynflete chair of physiology in the University of Oxford.

Born at West Hartlepool in 1878, Prof. Mellanby is the younger brother of Prof. Alexander Mellanby of Glasgow, and the elder brother of Prof. Edward Mellanby, F.R.S., secretary of the Medical Research Council.

Royal at the he sta he carried tion at qualifi for his he held the George Henry Lewes studentship at Cambridge, and devoted himself to physiological research on the coagulation of blood. He was appointed head of the department of physiology at St. Thomas's Hospital medical school in 1909, and was given the title of professor by London University in 1920. In 1929 he was elected a fellow of the Royal Society in recognition especially of his studies on the coagulation of blood and the mechanism of pancreatic secretion. He was editor of *Physiological Abstracts* from 1925 to 1935, and has acted as examiner at the Universities of Cambridge, Oxford, Leeds, and Sheffield, and for the diplomas of the Royal College of Surgeons.

University of Cambridge

Dr. Thomas Shirley Holo, lecturer in biochemistry in the University, has been elected master of Emmanuel College.

An entrance scholarship has been founded at Peterhouse which is restricted to candidates who intend to study medicine. It may be awarded for proficiency in mathematics, classics, natural sciences, or history. Further particulars will be found in our advertisement columns.

Society of Apothecaries of London

At recent examinations the following candidates were successful:—

Surgery.—C. N. Chowdary, Univ. of Durh.; P. D. Lynch, Guy's Hosp.; W. J. Pinto, Univ. of Madras; M. Q. H. Siddiki, Univ. of Leeds; and G. W. van Mentz and G. M. Williams, London Hosp.

Medicine.—R. H. Bembridge, King's Coll. Hosp., and A. Morgan, Univ. of Manch.

Forensic Medicine.—R. H. Bembridge, King's Coll. Hosp.; E. R. Jones, St. Mary's Hosp.; A. Morgan, Univ. of Manch.; and G. M. Williams, London Hosp.

Midwifery.—H. Burrows, Univ. of Manch.; E. M. Craggs, Middlesex Hosp.; F. J. H. D. de Marigny, Guy's Hosp.; M. G. H. Jones and J. R. Roeyn-Jones, Welsh National School of Medicine; M. Q. H. Siddiki, Univ. of Leeds; H. L. W. Sixsmith, Welsh National School of Medicine; R. L. Walmsley, Univs. of Camb. and Leeds; and C. W. Williams, Welsh National School of Medicine.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery: C. N. Chowdary, E. M. Craggs, A. Morgan, and W. J. Pinto.

Lectures for School Medical Officers

Two lectures for school medical officers on the diagnosis of congenital syphilis will be given by Dr. David Nabarro at the Hospital for Sick Children, Great Ormond-street, London, W.C., on Monday and Tuesday, Nov. 18th and 19th, at 2.30 p.m.

Royal College of Physicians of London

A Leverhulme scholarship of the annual value of £500 will shortly be awarded by the College. The scholar must undertake the investigation of some problem of disease in any branch of medicine. Further information will be found in our advertisement columns.

University of London

The title of emeritus professor of bacteriology in the University has been conferred on Dr. J. W. H. Eyre, formerly professor of bacteriology at Guy's Hospital medical school. Dr. Alexander Haddow has been reappointed Laura de Saliceto student.

University of Reading

At a congregation to be held on Dec. 2nd, when Sir Austen Chamberlain will be installed as Chancellor, the honorary degree of D.Sc. will be conferred on Sir Gowland Hopkins, O.M., P.R.S. Other recipients of honorary degrees will include Monsieur Horriot, Sir Robert Vansittart, Lord Rutherford, O.M., and Sir Joseph J. Thomson, O.M.

Scottish Conjoint Board

At recent examinations of the conjoint board of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow the following candidates were successful:—

L.R.C.P., L.R.C.S., AND L.R.F.P. & S.

M. R. Schleifer, S. H. Harrison, M. B. Spiegel, I. J. G. Mowat, Joseph Freeman, Harry Farber, Lot Hart, M. W. U. Alwi, John Orr, S. J. T. R. Murphy, Ruth Schurer, C. S. F. H. T. Rachlin, D. H. Abbott, Maria A. David Simon, M. S. Hendriks, R. C. G. B. Shirlaw, Sarah L. Mulholland, Otto Moses, Will Straus, C. J. Greenberg, A. E. Thompson, W. F. M. Unger, P. P. Perera, O. W. Nordesjo, D. S. Abeyagunawardene, John Jamieson, Abraham Berkow, Thomas Miller, J. E. Heller, Herbert Levy, Karl Melzer, Ralph Coff, H. G. Garas, Frances Hunter, Sanmugan Rajendram, Beate Isserlin, Solomon Marano, Ferenc Kellermann, and M. J. Philip.

Tuberculosis Association

A meeting of this association will be held at Manson House, 26, Portland-place, London, W., on Friday, Nov. 22nd, at 5.15 p.m., at which Sir StClair Thomson will speak on tuberculosis of the upper respiratory tract, and Mr. H. R. Bickerton on tuberculosis of the eye. The meeting will be resumed at 8.30 p.m., when Dr. E. L. Middleton and Dr. P. Hefernan will discuss industrialism and tuberculosis.

Society of Chemical Industry

A joint meeting of the London section and the food group of this society will be held in the rooms of the Chemical Society at Burlington House, Piccadilly, London, W., on Monday, Nov. 4th, at 8 p.m., when Prof. I. M. Heilbron, F.R.S., will deliver a Jubilee memorial lecture entitled *Chemical Elixirs of Life*. He will deal with recent developments in the chemistry of the sterols and related compounds.

National University of Ireland

A travelling studentship in physiology has been awarded to Dr. D. K. O'Donovan, University College, Dublin.

Ministry of Health

Mr. S. F. Wilkinson has been appointed assistant private secretary to Sir Kingsley Wood; Mr. T. W. Williams private secretary to Mr. Shakespeare; and Mr. J. E. Pater private secretary to Dr. MacNalty.

Scholarships for Sons of Medical Men

Two £100 scholarships are again being offered at Port Regis preparatory school to sons of medical men. The examination is being held in March, 1936, and candidates must be under nine years of age at the time of competing. Applications should be addressed to the headmaster, Port Regis, Broadstairs, not later than Feb. 20th.

War Relief in Abyssinia

The British Red Cross Society has received £5000 from Lady Ogle towards the organisation and dispatch of relief to the Ethiopian war zone. The total now in hand is some £19,000, and a small advance ambulance unit will leave London for Abyssinia about Nov. 17th. Further funds are urgently required for the maintenance and enlargement of this unit, and may be sent to Sir Arthur Stanley, British Red Cross Society, 14, Grosvenor crescent, S.W.1.

Children's Play Clinic at Guy's Hospital

In connexion with the department of medical psychology at this hospital a children's play clinic has been started. Toys are needed for the new venture.

Alford Memorial Cottage Hospital

Sir Lancelot Travers opened a new ward, new quarters for nurses, and an X ray department at this hospital on Oct. 18th. The extensions have cost over £2000, of which £1000 has yet to be raised.

Plymouth City Hospital

The foundation-stone of a new nurses' home for this hospital was laid on Oct. 16th. It is to be a three-storied building and will provide accommodation for 152 nurses. There will be a recreation-room, a library, a dance hall, and a laundry.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Nov. 5th.
Orthopaedics. 5.30 P.M. (Cases at 4.30 P.M.) Mr. H. J. Seddon: 1. Von Recklinghausen's Disease with Scoliosis. Mr. C. Hope Carleton: 2. Use of an Artificial Ligamentum Teres in the Treatment of Recurrent Shoulder Dislocation.
Pathology. 8.15 P.M. for 8.30 P.M. (Bernhard Baron Institute of Pathology, London Hospital, E.), J. O. W. Bland and Dorothy S. Russell: 1. Spongioblastoma Multiforme. Dorothy S. Russell: 2. Spinal and Ventricular Metastases in Spongioblastoma Multiforme. 3. Rare Intracranial Tumours. J. Gilmour: 4. Estimation by Planimeter of Relative Amount of Interstitial Tissue in Parathyroid Glands. Donald Hunter and H. M. Turnbull: 5. Osteomalacia in Various Conditions. F. C. O. Valentine: 6. The Effect of Staphylococcus Toxins on the Leucocytes of Human and Rabbit Blood. A. W. Downie: 7. Complement Fixation with Antipneumococcal Serum and Pneumococcus Polysaccharide. B. Woolf and J. R. Marack: 8. Cross Reactions of Type II. Antipneumococcus Serum with Synthetic Compounds of Glucuronic Acid. S. P. Bedson: 9. Experimental Psittacosis Pneumonia in Mice. H. Loewenthal and M. G. Gradman: 10. Colonial Forms of Hemolytic Streptococci.
WEDNESDAY.
History of Medicine. 5 P.M. Dr. E. J. Holmyard: The Pharmacology of Medieval Islam. A discussion, opened by Prof. J. R. Partington, will follow.
Surgery. 8.30 P.M. Mr. W. Sampson Handley: Paralytic Ileus in Acute Appendicitis (presidential address).
FRIDAY.
Clinical. 5.30 P.M. (Cases at 4.30 P.M.) Mr. J. E. H. Roberts (with Dr. A. J. Wilson): 1. Calcified Peri-

cardium with Ascites after Pericardiectomy. Mr. J. E. H. Roberts: 2-3. Total Pneumonectomy for Bronchiectasis. 4. Lobectomy for Bronchiectasis. Dr. R. C. Wingfield: 5. Spondylitis Rhizomelique. Dr. Gerald Slot: 6. Cases Illustrating Aurotherapy. *Ophthalmology.* 8.30 P.M. (Cases at 8 P.M.) Mr. J. H. Doggart: Fuchs's Epithelial Dystrophy.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, Nov. 8th.—8.45 P.M. (Miller General Hospital, Greenwich, S.E.), Dr. Charles Beney: The Chronic, Discharging Ear.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, Nov. 5th.—5 P.M., Dr. Daniel T. Davies: Peptic Ulcer (Bradshaw lecture).

THURSDAY.—5 P.M., Dr. J. D. Rolleston: History of the Acute Exanthemata (first of two FitzPatrick lectures).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Nov. 4th.—5 P.M., Dr. L. W. Proger: Some Diseases of Bone (II.).

FRIDAY.—5 P.M., Dr. A. J. E. Cave: The Anatomy and Physiology of the Human Larynx (II.).

JOINT TUBERCULOSIS COUNCIL.

MONDAY, Nov. 4th (Brompton Hospital, S.W.).—10 A.M., Dr. F. Lee Lander: Demonstration of Pleural Wash-out. 11.15 A.M., Dr. F. H. Young: A.P. Therapy for Pulmonary Tuberculosis in Ambulatory Patients. 2.30 P.M., Dr. W. E. Lloyd: Tuberculosis in Childhood. 3.45 P.M., Dr. J. L. Livingstone: Chronic Bronchitis and Emphysema.

TUESDAY.—10 A.M., Dr. A. L. Punch: The Value of Lipiodol in Diagnosis. 11.15 A.M., Dr. Clifford Hoyle: Chronic Miliary Tuberculosis. 2.30 P.M., Dr. J. V. Sparkes: Radiological Demonstration. 3.45 P.M., Dr. A. Hope Gosse: Difficulties in Diagnosis of Pulmonary Disease.

WEDNESDAY.—10 A.M., Dr. M. Davidson: New Growths of the Lung. 11.15 A.M., Mr. A. Tudor Edwards: Surgical Treatment of Pulmonary Tuberculosis. 2 P.M., Dr. Cecil Wall: Dry Bronchiectasis. 3.15 P.M., Mr. A. Tudor Edwards: Operations.

THURSDAY.—10 A.M., Dr. G. E. Beaumont: Demonstration of Cases: (a) Sedimentation. (b) Vital Capacity. (c) Sanoecrysin and other special drugs. 11.15 A.M., Dr. R. C. Wingfield: Relapse in Pulmonary Tuberculosis. 2.30 P.M., Dr. R. L. Rawlinson: Radiology of the Chest. 3.45 P.M., Dr. Geoffrey Marshall: Methods of Treatment of Pulmonary Tuberculosis and their Indications.

FRIDAY.—10 A.M., Dr. W. D. W. Brooks: Pneumokoniosis. 11.15 A.M., Dr. E. E. Atkin: Morbid Anatomy of Tuberculous Disease of the Lungs. 2.30 P.M., Dr. L. S. T. Burrell: Treatment of Pleural Effusions and Empyema. 3.45 P.M., Mr. F. C. Ormerod: Bronchoscopy.

SATURDAY.—10 A.M., Mr. J. E. H. Roberts: Surgical Treatment of Pulmonary Suppuration. 11.15 A.M., Mr. J. E. H. Roberts: Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Nov. 4th, to SATURDAY, Nov. 9th.—INFANTS HOSPITAL, Vincent-square, S.W. Mon., Wed., and Fri., at 8 P.M. Course for the F.R.C.S. (Primary) in Anatomy and Physiology.—St. PETER'S HOSPITAL, Henrietta-street, W.C. All-day course in Urology.—MEDICAL SOCIETY OF LONDON, Chandos-street, W. Thurs., 4 P.M., Dr. Norman Haire: Practical Contraception.—Courses and lectures open only to members.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Nov. 4th.—3.30 P.M., Dr. Carmichael: The Sympathetic Nervous System (I.).

TUESDAY.—3.30 P.M., Dr. Carmichael: The Sympathetic Nervous System (II.).

WEDNESDAY.—3.30 P.M., Dr. Kinnier Wilson: Clinical Demonstration.

THURSDAY.—3.30 P.M., Dr. Carmichael: The Sympathetic Nervous System (III.).

FRIDAY.—3.30 P.M., Dr. Bernard Hart: The Psychoneuroses (V.).

Out-patient clinic daily at 2 P.M.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 7th.—2 P.M., Dr. B. Shires: Treatment of Neri with Radium. 3 P.M., Dr. W. W. Payne: Diabetes (II.), Treatment.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Nov. 6th.—4.30 P.M., Mr. Kenneth Walker: The Treatment of Malignant Disease of the Genitourinary Tract.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL, N.W.

WEDNESDAY, Nov. 6th.—4 P.M., Dr. H. V. Morlock: Diagnosis and Treatment of Intrathoracic New Growths.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Nov. 6th.—3 P.M. (St. James' Hospital, Ouseley-road, S.W.), Dr. C. E. Lakin: Demonstration of medical cases.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, Nov. 4th.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Gynaecological and Surgical Wards, Eye and Gynaecological Clinics. 4.15 P.M., Mr. Green-Armytage: Menstrual Disorders.

TUESDAY, 10 A.M., Medical Wards. 11 A.M., Surgical Wards. 2 P.M., Throat Clinic. 4.15 P.M., Mr. Simpson Smith: Osteomyelitis.

WEDNESDAY, 10.30 A.M., Children's Wards and Clinic, Medical Wards. 2 P.M., Eye Clinic, Gynaecological Operations. 4.15 P.M., Mr. Gibb: Demonstration of Eye Cases.

THURSDAY, 10 A.M., Neurological and Gynaecological Clinics. 12 noon, Fracture Clinic. 2 P.M., Eye and Genito-urinary Clinics.

FRIDAY, 10 A.M., Skin Clinic. 12 noon, Lecture on Treatment. 2 P.M., Throat Clinic.

SATURDAY, 10 A.M.—Medical Wards, Children's and Surgical Clinics.

The lectures at 4.15 P.M. are open to all medical practitioners without fee. Operations and medical and surgical clinics daily at 2 P.M.

KING'S COLLEGE HOSPITAL, Denmark Hill, S.E.

New End Hospital, Hampstead, N.W.—Asst. M.O. £250.

Northampton General Hospital.—H.S. At rate of £150.

Norwich, Norfolk and Norwich Hospital.—Cas. O. £120.

Plymouth, Prince of Wales's Hospital, Greenbank-road.—Res. Anesthetist and H.S. to Special Depts. At rate of £120.

Prince of Wales's General Hospital, N.—Hon. Physician to Dept. of Physical Medicine.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Asst. Surgeon.

Queen.—Hospital, Marylebone-road, N.W.

Res.—Hospital. At rate of £200. Res. Anesthetist. At rate of £100. Res. Anesthetist and Dist. Res. M.O. At rate of £90. Also Asst. Res. M.O. At rate of £80.

Romford, Oldchurch Hospital.—Jun. Res. M.O. £250.

Rotherham Hospital.—H.P. £180.

Royal College of Physicians, Pall Mall East, S.W.—Leverhulme Research Scholarship. £500.

Royal Northern Hospital, Holloway, N.—H.S. and H.P. Each at rate of £70.

St. Helens Hospital, Lanes.—Jun. H.S. £150.

St. Mary, Islington, Hospital, Highgate Hill, N.—Asst. M.O. £350.

St. Pancras Hospital, Pancras-road, N.W.—Asst. M.O. £250.

Sheffield, Jessop Hospital for Women.—Asst. Hon. Surgeon. Also H.S. At rate of £100.

Southampton, Royal South Hants and Southampton Hospital.—H.P. At rate of £150.

Sunderland Royal Infirmary.—H.S. £120.

Swansea General and Eye Hospital.—Cas. O. At rate of £150-£175.

Wakefield, Scalebar Park Mental Hospital.—Asst. M.O. £650.

Walsall General Hospital.—H.P. and Res. Asst. Pathologist. At rate of £150.

West Bromwich County Borough.—M.O.H. and School M.O. £1000.

West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Registrar. £200. Also two Hon. Med. Psychologists.

West London Hospital, Hammersmith-road, W.—Res. Cas. O. At rate of £100. Also Physician to X Ray (Therapeutic) and Electrical Depts.

Wimbledon Hospital, Thurston-road, S.W.—Res. M.O. At rate of £150.

Woking and District Victoria Hospital.—Res. M.O. £120.

Woolwich and District War Memorial Hospital, Shooters Hill, S.E.—Two H.S.'s. Each at rate of £100.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Bingley (York, West Riding) and St. Annes-on-the-Sea (Lanes.).

A MODERN SCHOOL SANATORIUM.—On Oct. 26th Major-General W. P. MacArthur, R.A.M.C., opened a new sanatorium at Penrhos College for Girls, Colwyn Bay, Prof. Warrington Yorke, M.D., chairman of the board of governors, presiding. The building was designed by Mr. S. Colwyn Foulkes, M.Arch., A.R.I.B.A. The ground floor contains a private room for the resident doctor, a medical inspection room, matron's room, dental room, two four-bed wards, two two-bed wards, one single ward, two bathrooms, and linen room and kitchen. On the first floor there are the same number of wards, bed-rooms for doctor and matron, two maids' rooms, three bathrooms, a linen room, and the discharge and fumigation department. The sick-rooms, fitted with vitæ-glass, are grouped to the south and west, and every bed can be wheeled out on to the terrace or balconies.

NOTES, COMMENTS, AND ABSTRACTS

A STICKIT DOCTOR *

BY N. G. HORNER, M.D.

A PERSON whose life is spent half-way between two callings finds the temptation very great to choose a title such as Medicine and Letters or Some Literary Physicians, or (perhaps even more tempting) The Doctor in Detective Fiction. But, wondering what fresh stones were to be found in so well worked a quarry, I cast about for a topic less hackneyed that might entertain an audience made up largely of people on the threshold of medicine.

Looking back 30 years and more to student days, I remembered a novel that had some popularity among the simple-hearted reading public of that period—"The Stickit Minister," by S. R. Crockett. To a young English ignoramus the title was mildly provocative. Crockett's fellow-countryman, J. M. Barrie, had written a successful book and play, "The Little Minister," so we all knew what a minister meant in that context. It meant a Scotch clergyman. But I had to look up "stickit" in a glossary of Scottish words and phrases which said: "Bungled and spoiled in the making." One of Webster's dictionaries went further: "*Stickit*—stuck, unsuccessful, having failed, imperfect. *Stickit Minister*—a probationer who is unqualified for, or fails to obtain, a pastoral charge." Crockett had borrowed the expression from his hero, Sir Walter Scott. Poor Dominie Sampson in "Guy Mannering," was "a sort of person who might be the village school-master, or perhaps the minister's assistant"; he had studied for the Church, but upon his first attempt at preaching he "became totally incapable of proceeding in his intended discourse . . . and was ever after designated as a stickit minister."

A stickit doctor, then, is one who relinquishes the calling from want of ability or means to pursue it. There is no synonym for "stickit" in our southern vocabulary. "Botched," though a good English word, hardly meets the case. Have we not all met him in embryo at the hospital, or, later on, in his floundering after admission to the Register? He is the square peg in the round hole; the "chronic" who may at long last slip through the cordon of examiners only to make a hash of practice; the decent fellow who ought to have tried another job; or even the supposed duffer who discloses afterwards a genuine talent—perhaps real genius—in some quite different walk of life. At his worst the stickit doctor is the predestined failure in any profession.

The Doctor Outside Medicine

Let us first go over the names of a few of those who might be described playfully as "Can't Stick It" doctors—very able men who practised medicine for a time, or taught medical students, and then quitted our ranks for more congenial work in another field. There have been many such defections. In poetry a good example is Robert Bridges, a hospital physician for some years, whose "Testament of Beauty," published on his 85th birthday, Oct. 23rd. 1929, is still fresh in our minds. It has been said of Bridges that he was convinced that "he would be a better poet if he learned and practised some profession which brought him into active contact with human life, and particularly with the investigations and achievements of natural science." And 300 years earlier there was the poet and musician Thomas Campion, writer of charming lyric verse. In philosophy the outstanding English name is that of John Locke. Seventy years after Locke's death a young German named Schiller graduated in medicine on his way to immortality as poet and philosopher. Among

lawyers of recent times we recall the first Viscount Finlay, Lord Chancellor of England some 15 or 20 years ago, and note that two practising King's Counsel of to-day, Tom Eastham and Digby Cotes-Predy, are medical graduates. A small handful of church dignitaries—colonial or missionary bishops and a dean or two—must be reckoned in, and we cannot omit Dr. Livingstone, I presume. There is indeed a long list of medical travellers and explorers, from the time of Mungo Park onwards. Between his explorations in Africa, tracing the course of the Nile, Park practised for some years at Peebles.

Among living painters there are Henry Tonks, Slade professor of fine art in the University of London, 1917-30. Henry Lamb, and Perceval Yettis. Statecraft, politics, and public administration have claimed the redoubtable Georges Clemenceau, Prime Minister of France; Leander Starr Jameson, of South Africa, known in the 'nineties as "Brave Doctor Jim"; Leonard Wood, of the United States of America; Lord Ilkerton, one of Gladstone's lesser henchmen; Christopher Addison, Minister of Munitions, of Health, and of Agriculture; Auckland Geddes, the second of Lloyd George's cabinet anatomists, who held one ministerial post after another and then became British Ambassador at Washington; Walter Elliot, Minister of Agriculture to-day; and many other active members, past or present, of the House of Commons.

The stage took from medicine Charles Wyndham, Stephen Townesend, and Gilbert Hare, though Hare has long since gone back to his first love, bacteriology. Cricket was the chief occupation in life of the greatest of all cricketers, William Gilbert Grace, even if W.G. *did* like to brag in the pavilion at Lords about his "good practice down in Gloucestershire." Fiction and the writing of plays have lured away from us in my time Arthur Conan Doyle, Henry de Vere Stacpoole, William Somerset Maugham, Francis Brett Young, James Bridie (still known in the medical world of Glasgow as Dr. O. H. Mavor), Warwick Deeping, Austin Freeman, and A. J. Cronin, with Arthur Schnitzler in Germany, and Baron Henri de Rothschild in France. In the eighteenth century Tobias Smollett stood out as the one medical novelist when the art of the English novel was in its childhood: his "Roderick Random," "Humphrey Clinker," and "Peregrine Pickle," throw many sidelights on the health resorts, with shrewd comments on contemporary medicine. Without widening my net and narrowing its mesh to catch all the smaller fry of ex-doctors in literary waters, let me name a few medical naturalists whose writings on birds, beasts, and plants have given pleasure and instruction in the present century: Francis Darwin, Arthur Keith, F. Dawtreay Drewitt, A. F. R. Wollaston, Philip Gosse.

As for the members of our profession who have achieved eminence in the realm of pure science their name is legion. Medicine was the mother of the sciences. Where can we begin with them, or where end, even in our own country? William Harvey practised as a physician all the days of his working life; and the same might almost be said of Thomas Young, one of the greatest of English natural philosophers. Albrecht von Haller, physiologist, philosopher, poet, and statesman, graduated M.D. at Leyden. Thomas Henry Huxley took a medical qualification and taught medical students before he became one of the eminent Victorians whom Lytton Strachey forgot to belittle; with Michael Foster, Huxley ranks as physiologist and writer of English and as a fertilising influence upon the science of medicine. Charles Sherrington and Frederick Gowland Hopkins are with us to-day—successors to Lister and to Hans Sloane, the founder of the British Museum, in the presidential chair of the Royal Society. It is within this group, therefore, that we must place those men and women who obtain a medical degree without any intention of ever practising, because they mean to devote themselves to investiga-

* Abstract of paper read to the Listerian Society, King's College Hospital, October, 1935.

tion or teaching in one of the sciences allied to medicine but believe that the full medical course will widen their outlook. The word "stickit" does not apply to them. They have not failed at doctoring: they have taken our curriculum in their stride.

So we come to the practising doctors whose pens, from century to century, have enriched general literature. François Rabelais graduated as bachelor of medicine at Montpellier in 1530, and did well as a physician after—shall we say?—moderate success as a monk. The great name of Sir Thomas Browne, of Norwich, stands out also. "Religio Medici" was written to please himself and his friends in 1635, and he only published the authentic text eight years later because a pirated edition had already got into print. Then in the eighteenth century we find John Arbuthnot, friend of Swift and Pope and inventor of "John Bull," Samuel Garth, Mark Akenside, and Erasmus Darwin (grandfather of Charles). In the first half of the nineteenth century there was Peter Mark Roget, physician and savant, whose "Thesaurus of English Words and Phrases" finds a useful place on many a writer's bookshelf. John Brown, of Edinburgh, and Oliver Wendell Holmes, of Boston, were much-loved writers in the middle of the last century. After them came Silas Weir Mitchell, William Osler, Frederick Treves, and Ronald Ross, of the day before yesterday; and Henry Head, Axel Munthe, and H. H. Bashford of to-day.

Among the medical essayists and biographers Stephen Paget should perhaps be named here, because he had his plate up for years on a door in Harley-street and belonged to the staff of the Middlesex Hospital, though his heart was never really in the practice of medicine. There are also the medical historians and men of letters such as Norman Moore, Clifford Allbutt, and (still with us) D'Arcy Power, Raymond Crawford, and Andrew Macphail of Montreal. Nor must we forget the Victorian etcher and writer on art, Seymour Haden, who did his innumerable etchings in the spare time of a surgeon in active practice. To these men the arts, literary, historical, or pictorial, have been in greater or less degree the solace of their *hora subseciva* or by-hours. Few of them could be ranked as failed physicians, medical misfits, stickit surgeons. "Doctors, yet more than doctors" will perhaps serve.

But how difficult to draw a clear line. I hesitated whether to include John Keats with Campion and Bridges, and came to the conclusion that, like Oliver Goldsmith, this divine poet was truly a stickit doctor. Keats obtained the licence of the Apothecaries Society, but poetry was the only thing for which he really cared: "all other pursuits were to his mind mean and tame." High up on Parnassus, does his shade ever recall the drab mornings when he swept out the floor of the surgery of Mr. Hammond, to whom he was bound apprentice? Then we have the case of George Crabbe, physician, parson, poet; his practice at Aldeburgh was but a poor thing, and he gladly turned his back upon medicine. Goldsmith, Keats, and Crabbe, though they obtained medical qualifications, were unfitted to make use of them and soon dropped out. (There is some doubt about Goldsmith's M.B. but let that pass.) Charles Darwin, on the other hand, with ample family means at his back, gave up long before the final examination. The curriculum at Edinburgh failed to attract him; anatomy disgusted him, the operating theatre (in the days before anaesthesia) horrified him, and materia medica left on his mind "nothing but the memory of cold breakfastless hours on the properties of rhubarb." Robert Southey, poet laureate a hundred years ago, tried the study of medicine at Oxford, but found it or himself wanting and abandoned it in disgust. A later poet, Francis Thompson, had the same experience. Alfred Gilbert was a medical student before taking to sculpture, and perhaps gained something from his anatomical studies. Edmund Gosse came to London with the idea of reading for medicine.

Well, there they are: a random sample of stickit doctors who made good outside "the Physic Line." The list could be enlarged. In the time that remains I will leave literary allusions behind and offer a piece of worldly wisdom in the form of a short story. Here follows the fable or parable of a Stickit Doctor of the early twentieth century.

A Cautionary Tale

My contemporary—let us call him Y for short—was the nephew of a doctor, and it seemed right and natural to his widowed mother—and indeed to himself—that he should follow in the uncle's footsteps. Uncle William was a well-meaning but unimaginative man who had done tolerably well in the good old days of Victorian family practice in the "home counties." What way of life could be more appropriate for his young kinsman? So it was all tidily planned over the drawing-room fire by his elders when Y was in the Fifth Form. It never occurred to any of them to wonder whether Y was really cut out to be a doctor. Before leaving school he paid two visits to kind Uncle William, who gave him Gray's Anatomy, an old microscope, a box of bones, and some incomprehensible advice about elegant prescribing. In his first year of medical studies Uncle William died and a stranger bought the practice.

Having made a wrong choice of career Y fell into poor company. His fellow students were of all sorts, but those he chiefly mixed with took the short view. So he made a wrong approach to the science and art of medicine. He crammed for each examination and took many tumbles. No sooner did he jump a hurdle than he put behind him the facts he had got by heart and flung himself at new facts. Some of the facts turned out later to be fancies, but that didn't bother him: the exam. was the thing. He and his friends never perceived that the preliminary and intermediate subjects had a bearing upon the clinical part of the curriculum, to which they all looked forward. From beginning to end, right up to the final ordeal, he read nothing but "Aids" to this or that, and Synopses and short cuts of various kinds, and tried to memorise details in tabular form. His muddled reliance on "tips" was pathetic: they let him down time and again: *memoria technica* may be helpful to some of us, but Y often got the tip wrong at the critical moment in a "viva." When at length he reached the wards he became mildly interested in the patients and in the routine of clinical work. The spirit of the hospital got hold of him. But, as before, he lived from hand to mouth. He didn't read up his cases in Osler or Allbutt, and he let keener students finish off his cases or take his night duty. Need I say that he passed his midwifery examination at the first opportunity and then dismissed the subject from his mind?

In order to sum up Y's approach to the practice of medicine—his way of working for examinations—we may roughly paraphrase a description by Sir Theodore Mayerne of the habits of King James I. in matters of food and drink. He erred in quantity, quality, kind, order, time, and frequency. Poor Y, in short, took every wrong turning. He never even mastered the simple art of making a little knowledge go as far as it can be stretched. Examiners are human, and though it is said that you can't hoodwink them there is (or was) a method of persuading them to take the most charitable view of a candidate. Y didn't know that there was such a technique. He entered the examination room a minute or two after the clock struck nine, dazed and over-filled with undigested facts, after a frantic week of wet-cloth-to-the-brow reading. Five, or even ten, minutes spent in studying the paper and plotting out his three-hour course would have been well repaid. But no: Y started immediately upon the easiest question; ther. looking up at the clock too late he got flustered, miscalculated his time, left two awkward questions to the last quarter of an hour, and losing his head had to show up a blank sheet for one of them. The

and of thing happened during the laboratory at his papers he teased the long-suffering with endless repetition of one verb, "one adjective "marked," and one adverb ly." Then in the clinical examinations he put for a "spot diagnosis," throwing method in and forgetting that his main purpose was to prove that he knew how to go over and how to bring his observations to a focus, a little from his failures, which he put down as a check.

At last Y scrambled through the Final, only to find active life as a qualified doctor is full of traps and traps for the unwary. Dr. Douthwaite's little book "General Practice" was not then written, the British Medical Association had not published its handbook for the Newly Qualified nor THE B.M.A. its "Conduct of Medical Practice." In the week, before entering his name on the Medical Register or joining a medical defence society, he acted as a friend who was resident medical officer of one of the smaller hospitals—an institution supported wholly by voluntary contributions," the words of the Medical Act of 1858. And on its way back from the operating theatre to the surgery. When it came out at the inquest that the unregistered the coroner made some very remarks about Y and the hospital. A dozing Y woke up at this and his flying pencil made a copy for the lunch-hour edition of an newspaper.

Y will not wish me to follow Y through his life as a locum tenens in general practice of the district. But I might just recall the bad half-Dr. Z's dispensary in Shoreditch when Dr. Z turned found the stock mixture bottles nearly empty, the expensive tincture bottles nearly empty, and also the bad half-minute at Surbiton where A's best patient, Lady B, told Dr. Y what she thought of him for putting a pair of ice-cold hands on her treasured maid's abdomen. In her ladyship's opinion no examination of that kind was called for, it was unnecessary.

Y then went to the "death vacancy" which Y filled with borrowed money after superficial examination of the practice and no auditing of the books. He omitted to call upon the senior practitioner of the district or to mention his arrival to the secretary of the B.M.A. But at his first confinement in a lonely cottage on a winter night, his half-text-book knowledge failed him, and he turned to the senior colleague, a plain-spoken old man who was unaffectedly rude about "falling into a trap over a delayed first stage."

Y never learnt how to arrange his day's work, so he was often in slack times—and they were frequent—late for meals and unpunctual in attending at the cottage hospital to give anaesthetics or help at operation. He had a little stock of ready-made suggestions more or less by heart, but his attempts to apply one or other of these to the individual patient "case"—were not very happy. As for the general commercial travellers from the drug firms, electric-lamp makers and so forth, they found Y eager to try every unflinching synthetic remedy, every new piece of apparatus. On the other hand, Y was rather careless about keeping up with information from less interested quarters: he often forgot to read the newspaper and still more often forgot to read his weekly local newspaper—"What's the good of this prosy-brown stuff to me?"

Y would be wearisome to catalogue all the tactical mistakes that Y committed in the conduct of his work. There are very good doctors whose hold upon the patient and upon the patient's family is so firm that their shortcomings in the management of the practice do them little harm. Their personality and their professional competence make up for lack of aptitude in business. Not so with Y: he failed all round.

One evening an excessively female young person called on him after surgery hours and he saw her alone. The day the blackmailing mother dropped in for

a word with him. He belonged to neither of the defence societies, and had to employ an expert lawyer out of his own pocket to call the woman's bluff. This was a shattering experience. No wonder that when arranging for a consultation in those dark days he forgot to fix the fee beforehand, and heard with horror from Sir Thomas Guy Bart. on the patient's doorstep, that Sir Thomas's usual charge for coming to Muddleshire was—well, half this patient's income.

And now, to bring the sad story to an end, we reach an afternoon when Y, depressed and preoccupied, and all too conscious of the poor figure he was cutting in the medical profession, received a call from a plain but plausible stranger. This person paid without demur Y's modest fee for prescribing a course of colloidal cadmium (or it may have been vitaminised vanadium). Then he asked Y to sign his application for a passport. It was too late, he said, to hunt up a magistrate or a minister of religion, and the banks were closed: would the doctor oblige? All the particulars written on the form seemed to be in order; the photograph was painfully true to life; and Y fell into the trap. Thereafter meddlesome officials in England and abroad poked their noses into the matter. Police proceedings against the plausible stranger were followed by the appearance of Y before a tribunal, charged with putting his signature to a misleading declaration of "personal knowledge." They let him off with a grave caution, but Y had by now come to the conclusion that medicine was not his real job in life.

He understands dogs very well, and they tell me he has made quite a name in East Wessex as a breeder of Cairn puppies for the market. The explanation may be that a very sensible young woman took him and his affairs in hand just before it was too late, and now manages the household and the kennels with the tact and kindness and firmness which we all look for in a doctor's wife.

If I have over-coloured the case of Dr. Y, the moral is none the less plain. Anyone who seriously feels that he might become a stickit doctor should readjust his ideas, and if need be, rearrange his life—or else quit. But medicine offers many opportunities in diverse fields for different tastes and talents, and before turning his back upon it the man in doubt should take counsel with a wise and experienced elder.

DISTRICT NURSING IN ENGLAND AND WALES

AN interesting survey of district nursing in England and Wales, compiled by the Queen's Institute of District Nursing, provides a record of the district nursing service at present available throughout the country with details of its cost. Of the 62 administrative counties in England and Wales 60 are covered by county nursing associations, of which 10 are working independently and the remainder are affiliated to the Queen's Institute, and it is by the courtesy of the non-affiliated counties that information has been supplied which has rendered this survey complete. As is well known, the nurses giving domiciliary service are of two grades: (1) Queen's nurses, State registered, with an additional six months approved training in district nursing and if employed in midwifery the S.C.M.; (2) village nurse-midwives, i.e., certified midwives with some training in district nursing. The large part played by midwifery in the duties of district nurses is shown by the fact that during 1934, 68,519 midwifery cases were attended in England and Wales by 1019 Queen's nurses and 3068 village and other nurse-midwives. The maternal mortality-rate was 2.74 per thousand cases. During the period 1924-33, 606,545 cases were attended with an average mortality of 1.91 per thousand. Quite apart from midwifery there is increasing demand for trained home nursing care on the part of the medical profession, the local authorities, and the people themselves. A rough estimate made in 1926 suggested that, on a basis

DEATHS.

CARSMICHAEL.—On Oct. 24th, at Elvington, York, William John Carmichael, M.B., C.M. Aberd.

CRANE.—On Oct. 25th, at Kenilworth-road, Ealing, Horace Charles Frederick Crane, L.R.C.P. Lond.

FROST.—On Oct. 25th, at Lansdowne-crescent, W., William Adams Frost, F.R.C.S. Eng., Consulting Ophthalmic Surgeon to St. George's Hospital and the Royal Westminster Ophthalmic Hospital, aged 82.

PARK.—On Oct. 22nd, at Adel, Leeds, William Norris Park, M.B., C.M. Glasg., late of Carlton, Nottingham.

RUMBOLL.—On Oct. 23rd, at Melksham, Wilt., Charles Frederick Rumboll, M.D. Durh., J.P. D.J., aged 75.

SETTLE.—On Oct. 23rd, suddenly, in a nursing-home, Ian D. Suttle, M.D. Glasg., of Tavilton-street, W.C.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

THE NEW PURPOSE OF MEDICINE*

BY SIR GEORGE NEWMAN, G.B.E., K.C.B., M.D.,
LATE CHIEF MEDICAL OFFICER, MINISTRY OF HEALTH

THE science of medicine as we think of it to-day has emerged slowly, since the dawn of human history, out of a vast and complex medley of human experience, social as well as medical. We, the practitioners of the healing art in one branch or another in the twentieth century, are the indirect descendants of magicians, astrologers, witch-doctors, and priests, and our formulated doctrines derive from primitive folk-medicine and its plant-lore, and from the superstitions, charms, and spells of the ancient world five thousand years before Christ. But we no longer seek guidance from the stars and comets; we do not believe that disease comes by caprice or is caused by evil spirits or angry deities; and we belong to a profession which have transmuted the herbalism, bone-setting, and rude surgery of former ages into a growing and ordered science and art. It is true that all through the centuries its emergence has been permeated, as now, by human fallibility, ignorance, and error, but the history of its advance is, with all its faults, the history of the discovery or application of certain fundamental principles leading to a fuller understanding of the nature of man, of disease and its causation, and of the ways and means by which disease can be controlled and man's survival on the earth made a little less insecure and more purposive. This has been accomplished by the arduous labours of a long line of diligent workers devoted to the search for truth and a way of life. Their journey has never been continuous and not always progressive; sometimes it has been isolated and individual, at other times it has been coöperative, winning the assent of the commonalty of men.

Let me at once commend to all students and practitioners of medicine the essential and invaluable study of this fascinating story of what Osler called "man's redemption of man," one of the greatest stories in the history of mankind, a story of high endeavour of man's mind to find out the secrets of nature and the means of their fuller discovery, interpretation, and use. The history of a science, according to Prof. Sudhoff, is the science, and without regard to history there can be nothing but confusion, misapprehension, and wasted effort in our undertakings.

When we recall the medical practitioner of the ancient world or of the Middle Ages, or even of the Renaissance of the fifteenth century, and contrast him and his profession with the practitioner of our own time, we shall be arrested by the reflection that we are living in a period in the history of man which is characterised by a profound change in the purpose of medicine amounting almost to a revolution. It is becoming more communal and preventive. Not only has there been an enormous advance in knowledge in all branches of medical science, greater in the last hundred years, let us remember, than in all the centuries which preceded them, but two other modern changes have altered the application of such knowledge. The State has also availed itself of such knowledge in the interest of the whole people; and the education of the people themselves has enabled them to appreciate the advantages of such knowledge.

It is these three factors which have given the student of this generation a wholly new orientation.

THE MEDICAL CHANGES OF A CENTURY

Looking back a hundred years to 1835, the year of the passing of the Municipal Corporations Act which set agoing the practice of local government as we know it, we see a very different situation as compared with to-day. The principal medical events which brought England to the year of the great Reform Bill were significant. When, at the end of the fifteenth century, Linacre returned from his sojourn in Italy he was inspired with the idea of reviving English medicine with the Hippocratic learning of the Greeks; he began with the translation of the Greek masterpieces as represented in the writings of Galen; then he established Lectureships in Medicine at Oxford (Merton) and Cambridge (St. John's); lastly, he persuaded Henry VIII. in 1518 to found the Royal College of Physicians in London to introduce Greek Medicine and to regulate the practice of English Medicine. Subsequently the College issued the first official pharmacopœia for the authorisation and scrutiny of drugs used in medical practice. A century later, in 1616, Harvey announced to the College his discovery of the circulation of the blood which began modern physiology; Thomas Sydenham (sometimes called the Father of English medicine) introduced Hippocratic principles into his practice in London; lastly, there was the wonderful contribution of the medical practitioners of the eighteenth century. They studied and explored the circumstances of epidemic disease, introduced medical notification, advocated personal hygiene, initiated industrial welfare, reformed midwifery and the care of childhood, established dispensaries, hospitals, and medical schools, and gave to the world both John Hunter and Edward Jenner.

When therefore England reached the Reform period and the Municipal Corporations Act of 1835, English medicine was well established. But it expressed itself almost exclusively in private practice, and what was needed was (1) to bring its values into the national polity, and (2) to enhance those values. We have been the living witnesses of those two processes. We have seen at first a steady, and recently an extremely rapid, development of the services of the doctor to the nation, and parallel with it an almost incredible advance in medical knowledge. The first step was that the Poor Law Commission of 1834 at Edwin Chadwick's instigation employed medical men to explore the social and physical conditions of the poor. Chadwick's report on the sanitary condition of the labouring population became at once, and has remained ever since, an authoritative presentation of the medical aspects and needs of the social life of the people. It was followed by a long series of public inquiries and royal commissions in which medical men played a predominant part. In the result the State set up a central health authority (formerly the Local Government Board and now the Ministry of Health) and divided the country into sanitary districts, each governing itself on lines laid down by Parliament, and concerned with sanitation, water-supply, sewage disposal, housing, nuisances, the suppression of the causes of disease, food inspection, and the correct certification of sickness and death, which found expression in the Public Health Act of 1875 and four score of subsequent enactments.

* Inaugural address to the Welsh National School of Medicine, delivered at the Institute of Physiology, Cardiff, on Oct. 5th, 1934.

It is significant that as these Acts succeeded one another their contents became more personal, more direct, and more medical, so that to-day the public health services administered by the local authorities and their numerous medical officers are concerned, not only with the subjects of external environment already mentioned, but with health and disease—e.g., industrial welfare, maternity, infant welfare, the school medical service, the cleansing of persons Acts, the direct treatment of communal diseases (including fevers, tuberculosis, venereal disease, rheumatism, blindness, and lunacy), the provision of institutions (clinics, hospitals, sanatoria, special schools for defective children), a health and unemployment insurance system, medical research, the education of the people in health, international sanitary laws, and the *imposition of statutory duties on the medical profession in behalf of preventive medicine*. How great has been the expansion is indicated by the official report of the Treasury of the fact that in 1900 the nation spent 31 millions on public social services in England and Wales (education, public health, lunacy, poor relief), whilst in 1932, 30 years later, the nation spent 430 millions on these services (including insurance and pensions). Here is a gigantic scheme of national, social, and health enterprise for the welfare of the people, and with this scheme the medical profession is now intimately associated as adviser or agent.

The growth of medical science itself since 1835 is scarcely less impressive than the social and communal impulses which we have noted. There was the introduction of anaesthesia, the "death of pain" as it was called, followed by antiseptic surgery, the defeat of sepsis, hailed as two of the great discoveries of mankind. From 1845 to 1860 came the new knowledge from the labours of Helmholtz, Virchow, Claude Bernard, and Darwin. In that same period there were begun three series of investigations which have carried us whole leagues forward; Claude Bernard proclaimed the constancy of the internal environment of the body maintained by its circulating fluids, Du Bois Reymond opening up the problem of nervous regulation, and Addison that of endocrinology, and the three problems have been advanced and in part resolved in our own generation. There was the rise and rapid advance of bacteriology which opened the door to the work of Pasteur and Koch and their disciples, and in the last twenty years of the nineteenth century the discovery was announced of the bacillary cause of typhoid fever, septicaemia, tuberculosis, glanders, pneumonia, cholera, diphtheria, tetanus, meningitis, plague, and dysentery, and a little later came the spirochæte of syphilis. In 1895 came the unveiling of the body by the X ray; in 1898 Manson and Ross discovered the cause and vehicle of malaria; in 1900 the Curies isolated radium; and in the last thirty years we have seen that man himself is no longer the microcosm but the cell of which he is built is the unit. The cell, its content, its function, and its secretion, has become so vitally important that by its smallest deviation man's body may be profoundly changed, or even destroyed, by its own household. The advance of bacteriology has not only revealed the aetiology and viruses of infective processes but has opened the doors of immunology far wider than did Edward Jenner, providing us not only with vaccines and serums, but with diagnostic means of clinically estimating immunity. Physiologists and biochemists have elucidated the existence and character of the hormones in the body, finding their amazing power of control of the body to be second only to that of nervous

regulation; and in the world of nature have similarly been disclosed the vitamins; and as a result, we are now furnished with chemical and biological means of treatment and prevention. In 1909 Ehrlich gave us salvarsan as the chemical answer to syphilis, and in 1922 Banting furnished insulin as the biological answer to diabetes, and to these must be added medication by thyroid, adrenaline, pituitrin, liver extract, &c. We have in three generations seen almost a *new body* unveiled for man, and have begun to learn how to control his life. Truly, we are living witnesses of what Sir Clifford Allbutt called "a new birth of medicine."

What does all this mean for us? It means that in our day the science and art of medicine has arrived at a new position of immeasurable gain and advantage as compared with the past. We can now become, if we will, fuller interpreters of Nature, the heralds and agents of powers of control of the body undreamed of by our forefathers. In a word, the new purpose of medicine is *the prevention of disease in the individual and the community, and the raising of the whole standard of physical life and human capacity*. Let me submit for your consideration three reflections.

I. THE MAINTENANCE OF HEALTH

First, the art of medicine must direct its energy and knowledge to the maintenance of health. One of the recent changes that has come over the teaching of medicine is the necessity of studying anatomy, physiology, and even biochemistry in the normal living body, for the cadaver cannot be a vital index. We know that disease is a disharmony of the living body, its discomfort and dis-ease, its reaction to the constant internal environment of Claude Bernard and to the variable external environment which surrounds us—soil, air, water, climate, occupation, habits, and the agents of infection. One of the great lessons of the Greeks was that the body itself could often harmonise its disharmony, provided it could function normally. Now the normal body requires two natural conditions for its survival, functioning, and health—viz.: *nutriment* in the form of oxygen and nutritious food, and effectual *exercise* of all its parts and faculties. From the earliest times, however, the custom and education of the medical man has concentrated on morbidity, and this was reasonable as disease is the enemy of health. But it is not the only enemy, not the only criterion or agency of disharmony. There may be physiological disharmony. My submission is that doctors should enlarge the narrow purpose of directing their almost exclusive attention to morbid conditions and the remedy of such conditions mainly by means of drugs. Unfortunately this tendency in professional custom has misled public opinion, and the patient himself becomes accustomed to think in terms of disease and of drugs. Hence, there has arisen a pernicious and false reliance on the "bottle of medicine" or its proprietary patents. Literally, millions of pounds are being thus expended; in 1934 57 million prescriptions were issued under the Health Insurance Act. Drugs are sometimes necessary and a pharmacopœia is required. But medication by drugs is, like patriotism, not enough (or easily too much), and we must not lose our way in this direction, or surrender our common sense and neglect our new knowledge and better methods. If I may say so, the widespread fetish of quackery in its manifold forms may be partly due to the unconscious misdirection of doctors themselves. People are beginning to feel that they need something more than the doctors are giving them and therefore look elsewhere.

Thus a reaction is setting in. On all sides the community is begging for instruction and guidance from the medical profession as to health, something much larger than the negation of disease. On scientific grounds we know the common sense of this demand, and we should do wisely to meet it more fully. We know it is sound, because health of body means increase of capacity, physical and mental, for work and for the enjoyment of life; it means a stronger and better population, now and in the future; it means increased power to resist or overcome disease; and it means the prolongation of life and the postponement of death. I should like to see two things happen. First, that in every medical school there should be definite and skilled instruction in the applied physiology of the *nutrition* of the body (including dietetics), of ways and means of the effective oxygenation of the body, of *assessment of fitness*, physique, and capacity, and of all forms of *physical education*. This would encourage both the doctors and their patients in the new orientation of medicine. In some medical schools this is already undertaken, but it should be universal, and taken in hand by a clinical physiologist. Secondly, that every medical practitioner should actually include the practice of this form of clinical medicine. Mark this fact, *every patient needs health guidance*. Directly or by implication every patient, coming for the first time to his doctor, asks these four questions: "What is the matter with me; can you cure it; how long shall I have it; how can I avoid getting it again?" Here is diagnosis, treatment, prognosis, prevention. Each of these questions is of importance to the patient, but I invite you to consider the vast realm of medicine, and of invaluable service to the patient, which opens before you in providing a correct answer to the fourth question. In passing, you will observe that the patient, following his primitive ancestors, thinks of his malady as "it," something separate from himself an entity, an unlucky acquisition. But as we all know his malady is himself, a personal disharmony of his total ego. Disease is rarely singular, and perhaps never an entity. It is the man himself, his heredity, temperament, habits, way of life, perhaps even his religion, that is your patient.

Does the average busy practitioner actually advise upon or prescribe for the patient's way of life, his ineffectual use of diet (food and drink), fresh air, exercise, and rest? Has the doctor carefully considered the *physiological effect* of these five factors on his patient, on his heart, lungs, stomach, kidneys, on his nervous system, or his endocrine glands? Does he really answer the patient's fourth question, or does he evade it? Does not part, or the whole, of the patient's malady lie quite beyond medication by drugs? Is it not expedient that the patient, and indeed the normal person, should be able to obtain sound advice on health from the medical profession? Should not every practitioner be a missionary of health and prevention, a doctor and teacher of his patients in the true sense? It is certain that he could do more good in five minutes with his patient than any other educational agency, formal lectures, textbooks, or Acts of Parliament. In a word, I have been long convinced that medical practitioners ought to be, and often are, the first effective teachers of hygiene to a people, the principal interpreters of preventive medicine in England, for through their hands pass one-third of the whole population every year.

II. THE STATE AND THE DOCTOR

This leads me to my second reflection: As the nation has found by experience that the medical

profession is an invaluable ally in its schemes of governance, so it has increased its obligation upon them to serve the nation in preventive medicine. It began under the Tudors in 1511; by the Poor Law of 1601 the "parish doctor" was called upon to render medical relief to the statutory poor; and in the eighteenth century the State sought the advice of medical men in behalf of the national health. In 1838 the Poor Law Commission employed medical men to investigate the incidence and causes of fevers and other diseases, which were creating destitution; and in 1840 for public vaccination. A few years later came the appointment by local authorities of medical officers of health. From that time to the present, Acts of Parliament have greatly increased the statutory duties of registered medical men in respect of preventive medicine. They are required by law (1) to certify births, deaths and the causes of death; (2) to certify the occurrence of the major infectious diseases; (3) to certify cases of industrial poisoning; (4) to certify the existence of verminous children; (5) to observe the regulations affecting the issue and dispensing of prescriptions containing dangerous drugs; and (6) to give medical assistance in emergency at the request of a midwife. These obligations are made compulsory by the State on the assumption that every registered medical man is *competent* to determine the cause of death, able to diagnose all forms of infectious disease and industrial poisoning, knows the requirements of the Dangerous Drugs Acts, and is skilled in the diagnosis and treatment of obstetrical complications. Each of the six has preventive medicine in view. To these six must be added a number of corresponding liabilities. Any registered medical man may be called upon under Act of Parliament to vaccinate against small-pox, to act as a school doctor, a medical officer of health, or a medical officer for tuberculosis or venereal disease, to diagnose all forms of mental disease or deficiency, to certify and define public nuisances, to furnish factory and workmen's compensation certificates, and to provide on demand medical treatment for Poor Law or insurance patients. Again, most of these potential duties are preventive in purpose.

One of the most effective means of preventive medicine is the national health insurance scheme. This is a coöperative organisation between insured persons, the friendly societies, the medical profession, and the Government, especially designed for "insurance against loss of health, and the prevention and cure of sickness." The scheme is preventive in aim, and is proving to be so in practice; it is controlled by medical and lay coöperation, the greatest scheme of medical collective responsibility yet tried in Britain. Consider what is happening. Sixteen thousand doctors (some 70 per cent. of the medical practitioners in England and Wales) have agreed to accept their right (which they need not exercise), under the Act to give *preventive* and curative advice and treatment to sixteen million insured persons. The doctor is paid for each person on his panel, whether he becomes a patient or not; the patient has free choice of his doctor, and may come at the very beginning of his sickness, without let or hindrance, undeterred by any question of fee; the doctor's duty is to diagnose and treat the illness, the facts of which must be recorded by him; he inquires as to causation, because it pays him best for his client *not* to be ill; he must estimate resultant incapacity, because that is necessarily the basis of benefit; and he must treat effectively, for a dissatisfied patient changes his doctor. There is some imperfect work

no doubt and some complaints (as in all medical practice) in a scheme so vast though as yet incomplete, but taken as a whole this system provides medical services for half the adult population of the realm—and infinitely better than under the former "club" practice—and there need be no doubt whatever as to its preventive value.

Here are quoted a score of Acts of Parliament with as many amending Acts, most of them dealing with clinical duties and all of them designed not to control the form or character of the treatment of disease, but to ensure its *prevention*. In 1933 (the latest year for which figures are available) there were certified by medical men upwards of 330,000 cases of infectious disease, the cause of 496,000 deaths, and seven or eight million insurance patients as to "incapacity" and claims for benefit. Of this third group there were referred back to the Ministry of Health by approved societies and insurance practitioners 540,000 cases for decision or consultation, a very significant figure. Upon this national system of correct medical registration of sickness, prognosis, and death depends the fabric and effectiveness of the public health service of England and Wales. Innumerable difficulties and dislocations of public welfare follow in the train of inaccurate diagnosis of sickness, mistaken assessment of physical fitness, or the incorrect certification of the causes of death.

III. NEED FOR MORE PREVENTIVE MEDICINE

The last reflection I submit for your consideration is this. Although the death-rates in this country are exceptionally low, and lower than in most countries of the world, and the national health has steadily improved and stands higher to-day than at any previous time in our history, and although England has banished leprosy, plague, cholera, epidemic enteritis, endemic scurvy, typhus, and other scourges, and although the nation is spending lavishly on social welfare, there is still great need for further progress in preventive medicine and its research. We have as a nation by no means solved all our health problems, and our industrial and social evolution seems to bring new ones. The physique of children, although improving, leaves much to be desired, and that of youths from 14 to 18 years of age shows some signs of actual deterioration in certain districts; nutrition has steadily improved, but is still very unsatisfactory in some groups of the population; the common cold, bronchitis, and dyspepsia continue prevalent, costly, and disabling, yet all three are among the most preventable of maladies; influenza, "rheumatism," and cancer remain undefeated, and diseases of the heart and circulation claim 130,000 lives a year (much the highest certified cause of death); maternal mortality remains static at about 1 death in 200 mothers confined and shows as yet no reduction; the dental condition of the people is very much below par and results in unfortunate sequelæ; and too much attendance upon the sick is directed merely to drugs and ineffectual advice rather than to personal hygiene and a sound way of living. It must be added that the burden of incapacitating sickness and accident continues to be unduly heavy, costs the nation annually millions of pounds, and deprives industry of many thousands of years of lost time from work—in 1933, 29 million weeks were thus lost. The great bulk of this current sickness and accident is directly preventable by a sensible, intelligent, and civilised people, but it is not prevented. These are serious facts for the consideration of the profession. We cannot ensure a healthy nation only by "bottles of medicine," modern surgery, and artificial immunisa-

tion. A fuller and deeper appreciation of positive and constructive health is necessary.

In the light of these facts I venture to hope that the medical profession will steadily continue to close its ranks and work together as one body for the unity of medicine. It has in practice two aspects or wings, curative and preventive, between which there is now no call whatever for any sort or degree of conflict or competition. They are complementary and belong to each other, as the wings of a bird. *They need each other, and the community needs both.* Moreover, the medical practitioner is the outpost of both. We must use the new knowledge so rapidly extending in order to serve the national health. In doing so, we should remember that the social, æsthetic, psychological, and religious aspects of man's health or wholeness cannot wisely be disregarded. They form an integral part in the formation of those common standards of aspiration, discipline and conduct, so greatly needed by the nation to-day, and so essential to national health. Among such standards, to be accepted by the public and to be vigorously supported by the medical profession, none seem to me to be more vitally important than the urgent national need for the physical and health education of youth. Some other nations are rapidly providing this by order of Government. If we in Britain do not thus provide it by Act of Parliament the obligation upon our voluntary service is all the greater.

CONGENITAL AND RECURRENT DISLOCATION OF THE PATELLA

TREATED BY TRANSPLANTATION OF THE PATELLAR
TENDON

By FRANK FORTY, M.B. Lond., F.R.C.S. Eng.
RESIDENT SURGICAL OFFICER, GENERAL HOSPITAL, BIRMINGHAM

AMONG patients presenting themselves on account of mechanical defects of the knee-joint a small group is found to be due to malpositions of the patella. The most common is that known as "slipping patella," in which recurrent dislocation occurs, almost always on to the external femoral condyle, when the knee is fully extended. There is rarely any difficulty in reducing such dislocations, but the frequency of the occurrence results in a serious disability which needs some sort of operative measures for its relief.

Less commonly the dislocation is a permanent one, the patella occupying a position on the outer side of the external condyle of the femur, from which it cannot be manipulated into the intercondylar groove. In association with this defect a variety of other deformities are usually present in and around the knee-joint. Such are a subnormal development of the prominence of the external condyle of the femur; insertion of the patellar tendon into the lateral aspect of the upper part of the shaft of the tibia; absence of the normal projection of the tubercle of the tibia; and varying degrees of dystrophy of the patella itself, amounting in extreme cases to complete absence of this bone.

Permanent dislocation of the patella, with or without dystrophy, is not attended by recurrent disablement as is a "slipping patella," and is indeed compatible with a surprising degree of efficiency of the knee-joint. Nevertheless appreciable loss of power of extending the knee-joint, together with persistent pain, presumably due to the abnormal stresses to which such a joint is subjected, are

sufficiently embarrassing to the patient to justify operative treatment, if something like normal function can thereby be obtained. That this is indeed possible by means of a relatively simple operation is shown by the case (No. 1) reported below.

There can be little doubt that the deformities which we are considering are of congenital origin. In a considerable number of the recorded cases the condition appeared to be hereditary, being recognised in several generations of the same family.^{1,2,3} The interesting suggestion was made by Malkin⁴ that congenital dislocation of the patella might be considered to arise as a consequence of the adoption of the erect posture by man. Man alone stands with the knees fully extended. In order that the tibiae shall be close together and parallel in this position, the inward inclination of the femora, making their axes converge toward the knees, is neutralised by the tibiae being set at a slight obtuse angle outwards with the femora. This angle, as is well known, disappears when the knees are flexed. The quadriceps muscle, with its insertion via the patellar tendon, shares in this angular conformity of the limb, and in full extension winds outwards around the projecting anterior surface of the external condyle of the femur, as around a pulley.

Malkin draws attention to the fact that in the sheep and the ox, which walk with bent knees, the internal condyle of the femur is more prominent than the external, that in the gorilla the two condyles are approximately equal, and that in man alone is the external condyle the more prominent. He supposes that a subnormal development of the external condyle would, at the first full extension of the knee-joint, allow the patella to slip laterally out of the intercondylar notch on the external aspect of the femur, where it is subsequently found in cases of congenital dislocation.

TREATMENT

Various methods of operative treatment have been

advocated for dealing with dislocation of the patella. The operation which has given uniformly successful results in the cases here reported is based on the principle of displacing the insertion of the patellar tendon to a more medial position on the tibia, so giving a new line of direction to the quadriceps muscle and patellar tendon. The patella is thus brought permanently between the femoral condyles. At the same time a pedicle graft is taken from the inner side of the joint capsule and transplanted into the outer side of the capsule. The resulting narrowing of the inner side of the capsule serves to anchor the patella in its new position.

The essential steps of the operation may be summarised thus:

1. An incision is made along the outer side of the knee, curving inwards at the lower end.
2. The skin and subcutaneous tissue are reflected off the front of the knee-joint.
3. The patellar tendon is defined, and separated from the rest of the capsule by medial and lateral incisions which open the knee-joint. On the medial side, a Λ -shaped strip of capsule and synovial membrane (Fig. 1a) is isolated, and left attached by its base to the front of the tibia.
4. A square of bone (B), which includes the insertion of the patellar tendon, is lifted by saw and chisel cuts from the front of the tibia.
5. A second square (C), of exactly similar size, is removed from the front of the tibia immediately medial to the first one (B).

FIGS. 1 and 2.—Illustrating the operation of transplantation of the patellar tendon.

FIG. 3.—Photograph of knees before operation, showing position of small laterally placed patella (Figs. 3 to 6 illustrate Case 1).

FIG. 4.—Radiogram of knees before operation. The shadow of the small laterally placed patella has been outlined for greater clearness.

6. The squares of bone are replaced so as to transpose their positions, thus giving a more medially situated insertion to the patellar tendon (Fig. 2). The secure wedging in position of these two squares of bone obviates the use of any screws.

7. The opening thus left in the medial side of the capsule of the knee-joint is closed with a continuous catgut suture.

8. The Λ -shaped strip of capsule (A) is swung over to the lateral side of the joint, and sutured so as to fill the gap on that side. The last two steps result in a reduction of the width of the capsule on the medial side. The Λ -shaped strip (A) crosses the new insertion of the patellar tendon, and as it is here sutured to the aponeurosis, it helps to keep the detached squares of bone (B and C) in position.

9. The skin wound is closed by interrupted silk-worm gut stitches. The limb is immobilised on a splint until the sutures are removed, when massage of the quadriceps is commenced.

The operation, thus performed, closely resembles that described by Wagner,⁵ who however does not include the synovial membrane in his Λ -shaped strip, and so avoids opening the joint.

Following are reports of three cases.

I

A. B., male aged 27 years, labourer, was admitted to the General Hospital, Birmingham, on June 15th, 1932.

History.—There were no symptoms until the age of 14 years. He was able to play football at school. He had been troubled by pain and "stiffness" of both knees for the last 13 years, but this had become much worse of late. Nine brothers and sisters were all normal.

Examination.—The following points were noted: Prominence of internal condyles of femora, absence of tubercles of tibiae, very small patellae situated on the outer aspects of the knee-joints (Fig. 3). Passive movements were free and painless, and a full range of flexion and extension was obtained. Active extension of the

FIG. 5.—Photograph of left knee before operation, showing maximum degree of active extension possible in the sitting position, and position of small laterally placed patella.

knee from the sitting posture was severely limited. Fig. 5 shows the maximum degree of active extension possible before operation.

X ray (Fig. 4) shows: Hypoplasia and external dislocation of patellae, absence of tubercles of tibiae, and genu valgum.

Operation, as described above, was performed on the right knee by Mr. Leather on June 21st under general anaesthesia.

Results.—Fig. 6 is a photograph taken more than two years after the operation. It shows that the knee can now be fully extended by active muscular contraction, without dislocation of the patella from the intercondylar groove. The knee has not been painful since the operation, and has shown no tendency to give way.

The operation on one knee only has caused such an improvement in the patient's gait and stability,

FIG. 6.—Photograph of left knee after operation, showing restoration of full range of active extension of the knee-joint.

that he is now able to follow his occupation without difficulty. It is proposed to perform a similar operation on the other knee at a later date.

The two following cases are quoted as examples of the successful treatment of recurrent dislocation of the patella by the operation as described above:—

II

C. D., female, aged 17 years. Admitted Sept. 25th, 1932.

History.—Recurrent dislocations of left patella during the past 12 months. This first occurred as a result of jumping and landing heavily on both feet.

Examination.—There was abnormal laxity of the capsule of the knee-joint. The patella could easily be dislocated outwards.

Treatment.—Massage and faradism to the vasti caused no improvement.

Operation.—By Mr. Leather, Sept. 27th; transplantation of insertion of the patella tendon.

Result.—There had been no recurrence of the dislocation 18 months after the operation. All movements of the knee-joint were free and painless.

III

E. F., male, aged 20 years. Admitted to the General Hospital, Birmingham, Oct. 28th, 1933.

History.—Attacks of pain had occurred in the right knee, since it had been injured in falling off a bicycle six months before admission. At 5 years of age—operation for genu valgum.

Examination.—Right knee—patella permanently displaced to outer side of knee-joint. Movements were free, but some grating was felt.

Operation.—Nov. 3rd, by Mr. Leather. Transplantation of insertion of patellar tendon.

Result.—Movements of knee-joint free and painless. Patella has remained in the intercondyle groove.

I am much indebted to Mr. J. B. Leather, for permission to record his cases, and to Dr. Harold Black for the radiograph.

THE THERAPEUTIC APPLICATION OF PHENYLMERCURIC SALTS

OBSERVATIONS ON THE USE OF BASIC PHENYLMERCURIC NITRATE IN GYNÆCOLOGY

By LEONARD H. BISKIND, M.D.

(From the Gynecological Service, Mount Sinai Hospital, Cleveland, Ohio)

Robert Otto,¹ a German chemist, synthesised phenylmercuric nitrate (now known to be basic phenylmercuric nitrate) in 1870. For over half a century this substance was neglected. Some of its chemical properties were known, but it was not until sixty-one years later, in 1931, that Weed and Ecker² (after four years' investigation) reported the successful preparation of this and other phenylmercuric compounds in a purified state. They pointed out that basic phenylmercuric nitrate combines a very high bactericidal potency with a relatively low local and systemic toxicity for animals and for man; that very high dilutions of an aqueous solution exert a strong disinfecting and antiseptic power on bacteria and moulds; that its effectiveness is not impaired by the presence of tissues or tissue juices; that it is very slightly irritant on local application to wounds and most mucous membranes; that it has no odour and colour and does not stain; and that it does not corrode surgical instruments.

In 1932-33 Weed and Ecker^{3,4} reported further on the chemical and biological properties of the phenylmercuric salts, and in 1933 Birkhaug⁵ independently confirmed their original work. He stated:

"Because of its high bactericidal action, low toxicity, general diffusibility and inability to precipitate serum or tissue proteins (basic) phenylmercuric nitrate appears to be useful in the production of bacteriostatic action in the biliary, cerebro-spinal, genito-urinary and vascular tracts. The alcohol acetone aqueous 0.034 per cent. tincture of (basic) phenylmercuric nitrate has a superior value as an efficient non-deleterious and powerful pre-operative skin disinfectant. This mercurial solution is relatively free from the many objectionable features of tincture of iodine and the alcohol acetone aqueous 2 per cent. solution of mercurochrome."

The Council of Pharmacy and Chemistry of the American Medical Association,⁶ in a preliminary report on basic phenylmercuric nitrate and phenylmercuric chloride, stated that:

"Test-tube experiments have shown that (basic) phenylmercuric nitrate is a powerful germicide and fungicide of wide ranging effect and relatively low toxicity. Fewer tests have been made with phenylmercuric chloride, but it seems likely that the two compounds are equally active. Experiments with animals indicate that the ingestion of (basic) phenylmercuric nitrate may lead to strong bacteriostatic and bactericidal effect in the blood, cerebro-spinal fluid, bile, feces and urine. It seems to be clearly indicated that (basic) phenylmercuric nitrate can disinfect skin, disinfect instruments without corroding them and preserve biologic products against bacterial growth without destroying their specific properties and actions."

In 1933 Armangue and Maestres,⁷ working in Barcelona, Spain, reported a new technique for the synthesis of phenylmercuric salts. Hatfield,⁸ in 1932, studied 16 mercurials, including two of the phenylmercuric salts and their particular effectiveness against wood-destroying fungi. He showed conclusively that the effectiveness of basic phenyl-

mercuric nitrate and phenylmercuric chloride was markedly superior to that of all the other mercurials studied. In 1934 Pyman and Stevenson⁹ demonstrated that the phenylmercuric salts used in the investigations of Weed and Ecker and of Birkhaug were the basic salts, the compound thought to be the nitrate actually being $C_6H_5HgOH \cdot C_6H_5HgNO_3$.

In a second publication Armangue and Maestres¹⁰ reported on the construction and bacteriological properties of other phenylmercuric salts. They prepared the benzoate, borate, lactate, citrate, phenate, phosphate, oleate, oxalate, picrate, salicylate, sulphate, and tartrate in addition to the previously constructed chloride and basic nitrate. All these salts were studied for their bacteriostatic and bactericidal effects on 13 species of organisms. Because of the fact that it was found to have the least irritating effect and that it was more soluble than the basic nitrate, these investigators chose the borate for extensive clinical studies and found this particular salt superior to anything thus far developed. Armangue and Maestres stated that: "Clinical trials on the practical utility of (phenylmercuric borate) attempted by a legion of investigators has given astounding results which indicate that the (phenylmercuric borate) is an acquisition of positive value in human therapy."

In January, 1935, Stark and Montgomery,¹¹ working with basic phenylmercuric nitrate, indicated that the active bactericidal component was the C_6H_5Hg ion and stated that this differed from other organic mercurial compounds used as antiseptics in that the mercury atom was in the cation. Since bacteria are usually negatively charged, this positive charge of the phenylmercuric ion may be a factor in its high inhibitory power. Bacteriostatic effects were studied by the methods of Kolmer as modified by Birkhaug. Their results confirmed the findings of Birkhaug in which the latter showed the extremely high inhibitory powers of this salt when small numbers of organisms were employed. The germicidal effects were determined by the Shippen modification of the Food and Drug Administration method.

In comparing phenylmercuric salts as prepared by the method of Weed and Ecker and the same products as prepared by methods used by some commercial manufacturers, it is highly important to note that, as pointed out in the report of the Council on Pharmacy and Chemistry,⁶ Weed has expressed the opinion that the compounds obtained from several manufacturers are not as satisfactory as the compounds prepared by him or according to his method under the supervision of himself and Ecker. The basic phenylmercuric nitrate used in my own work was originally provided by them, and the subsequent material in a similarly highly purified form was furnished by the Hamilton Laboratories, Inc., Hamilton, Ohio, who market this product at present under the trade name Merphenyl Nitrate (Basic).

In 1931, at the request of Dr. Ecker, I undertook a study of the use of this product in gynæcology. The opportunity was given to me of treating 100 cases of specific and non-specific endocervicitis and associated conditions both at Mount Sinai Hospital and at the House of The Good Shepherd in Cleveland. The results¹² showed an invariably favourable response in all the conditions encountered, both specific and non-specific, except when *Trichomonas vaginalis* was the inciting agent. It was noted that the character of the infection could be changed, often by a single application, and that even when complete and rapid clinical recovery was not attained

there was enough improvement to allow of the successful use of adjuvant treatment. In effective concentrations, both as local application (1:1250) and as a douche (1:25,000), basic phenylmercuric nitrate was non-toxic, and almost non-irritant to the vaginal mucous membrane, and it proved effective in the presence of tissues. When it was used persistently as a douche the patients did not develop symptoms of mercury poisoning and the output of mercury in their urine was negligible.

Miss N. E. Schreiber, of the department of pharmacology, Western Reserve University, determined by a highly sensitive microchemical method the mercury content of 24-hour urine specimens from patients in this series of cases who had been douching with the 1:25,000 solution once or twice daily for six weeks. In three specimens examined the mercury output ranged from 0.008 to 0.014 mg. Judging from the work of Sollmann¹² and his associates, this represents an entirely negligible output. Where significant quantities of ionised mercury are absorbed, as in lactic therapy, the urinary excretion of the metal is very much greater than that found in these cases.

In this paper I wish to report the results of the subsequent use of basic phenylmercuric nitrate in private as well as dispensary practice.

CONDITIONS TREATED AND METHOD OF TREATMENT

Of the 63 cases reported here, 41 were seen in the dispensary and 22 in private practice. The former comprise 11 cases of vaginitis in children (5 gonorrhœal and 6 due to a mixed infection, including 1 due to *B. coli*), 13 cases of *Trichomonas vaginalis* infection in adults, 14 cases of endocervicitis (7 gonorrhœal and 7 non-specific), 1 case of recto-vaginal fistula, 1 case in which a slough followed vaginal hysterectomy, and 1 case of paracervical sinus with infection following cauterisation. The latter group consists of 11 cases of gonorrhœal endocervicitis, 2 of trichomonas infection, 4 of non-specific vaginitis, 4 of non-specific endocervitis, and 1 case of tinea infection involving the perineum and labia.

Certain changes in technique have been made since my preliminary report.¹²

The basic phenylmercuric nitrate used in the treatment of all the present cases was an aqueous 1:1500 solution. That given to the patients for dilution in the preparation of the douche was a 1 per cent. solution in diethylene glycol. The latter was dispensed in 2-oz. bottles and the patients were advised to use a drachm (4 c.cm.) to a quart of comfortably warm water, making approximately a 1:25,000 solution for use as a douche. The use of a tampon saturated with the concentrated aqueous solution was discontinued and treatment was confined to the cleansing of the urethra, vagina, and cervix, the instillation of basic phenylmercuric nitrate (1:1500) and the use of the daily douche as described. The necessity for douching slowly and thoroughly in the semi-recumbent position, preferably in the bath tub, was stressed. In addition, each patient was questioned as to her method of cleansing following bowel movement and in those cases in which the method was faulty, proper instructions were given to prevent faecal contamination of the introitus. It is surprising to note the tremendous number of women and girls both in dispensary and private practice who have never given a single thought to the proper method of cleansing the anus after defecation.

In the treatment of vaginitis in children the following method was used:

The labia were separated and an endoscope was inserted where possible. A smear was taken by inserting a very small, dry, sterile swab into the vagina. Subsequently, a blunt 2 c.cm. syringe was used to instil approximately 1 or 2 c.cm. of the 1:1500 solution of basic phenyl-

mercuric nitrate directly into the vagina. The hips were elevated for a few minutes to prevent the medication from running out. The mother of the patient was instructed to make a 1:25,000 solution of basic phenylmercuric nitrate (as outlined above) and by using an infant enema tip or a soft rubber catheter to irrigate the vagina once or twice daily using a pint of the solution each time. In order that the mother might fully understand the method, a visiting nurse was sent to the home the first day to instruct her in the technique.

VAGINITIS

Eleven cases of vaginitis were seen at the dispensary of Mount Sinai Hospital in children ranging from 4 to 15 years of age. Five were clinically and microscopically gonococcal in origin; one was due to *B. coli*, and the remaining five were non-specific microscopically. When treatment with basic phenylmercuric nitrate began the infections had been present for 1-6 months, and all but one had had at least one other form of treatment (usually hexylresorcinol instillations). The success obtained with the new remedy was really gratifying. The severest cases were free from subjective symptoms within a very few days, and I have been able to discharge these youngsters, with no signs or symptoms and with negative smears, as soon as six weeks from the onset of treatment. Strange as it may seem, the cases of specific vaginitis cleared up a good deal more quickly than the non-specific. Two cases in the latter group had been reinfected.

One was a child of 6 whose original infection cleared up in six weeks. She remained symptom-free for four months, and then returned with a reinfection, again non-specific. A second course of treatment as outlined produced a cure in three and a half months. The second child, aged 10, also had a non-specific vaginitis. After eight weeks of treatment she remained symptom-free for three months, but returned with a reinfection; this was completely eradicated by intensive therapy in two months.

In both cases the reinfection was attributed directly to improper cleansing of the anus after defecation. Both children have now been symptom-free for 18 months.

A typical case will serve as an example of this group.

A girl, aged 11, was referred to the gynaecological service from the paediatric service, Nov. 21st, 1933, because of a persistent vaginal discharge of three weeks' duration. Vaginal smears taken on the first visit to the gynaecological dispensary were positive for gonococci. This youngster had no previous treatment of any kind. Following the method as outlined herein, therapy with basic phenylmercuric nitrate was instituted. On the second visit four days later the mother reported a very definite lessening of the discharge, with a change in colour from a yellow-green to milk-white and a change in viscosity from tenacious to watery. Endoscopy corroborated this report. Continuation of the intensive treatment until Dec. 4th, 1933, permitted the child to return to school symptom-free. After four more weeks of treatment in which the intervals between treatments and douches were gradually lengthened, she was discharged. Six months later she was still free from symptoms and vaginal smears were negative.

In private practice I encountered 4 cases of vaginitis, non-specific in origin, 3 in adults and 1 in a child. The former group comprised a case of senile vaginitis with secondary infection, a case of vaginitis following the prolonged use of a Smith-Hodge pessary, and a case of vaginitis due to faecal contamination. In all of them instillation of basic phenylmercuric nitrate with daily douching made the patients free from signs or symptoms. A case of

chronic vaginitis recently reported by Hitchings¹⁴ bears out my contention that basic phenylmercuric nitrate will change the character of the infection within 24 to 48 hours. Although it may not always be possible to clear up the source of the infection, as in deep-seated chronic cervicitis, the use of this antiseptic will improve the patient subjectively and objectively and will permit the successful use of adjuvant treatment.

TRICHOMONAS INFECTION

In a previous report I mentioned that the use of basic phenylmercuric nitrate in two cases of *Trichomonas vaginalis* infection gave poor results. Thinking that prolonged intensive therapy might prove effective, I reinvestigated this problem. A total of 15 cases, diagnosed microscopically, were treated by instillations of basic phenylmercuric nitrate three times weekly and the use of douches twice a day. Of this number, 13 were seen at the dispensary and 2 in private practice. In each case the urine, as well as the vaginal discharge, was examined for the protozoan. In 2 cases of recurrence the stools were checked in a similar manner. Realising that reinfections are common in this particular condition and that, it has been said, about one-fifth of these arise from faecal contamination, I thought it advisable to be particularly careful in pointing out to these patients that the utmost care must be taken in cleansing the anal region following defaecation.

Among the dispensary cases the most rapid recovery occurred in a 35-year-old patient who was seen for the first time on Nov. 8th, 1933, with a typical thin, frothy, greenish-yellow discharge and punctate hæmorrhagic areas in the cervix and adjacent areas; examination of a hanging-drop preparation revealed the presence of *T. vaginalis*. She had had no previous therapy. Treatment with basic phenylmercuric nitrate was instituted and one week later the patient was much improved. The inflammatory process had cleared up completely and there was only a very slight milky leucorrhœa around the cervix. Ten days later the patient had no discharge; the cervix and vagina looked normal. A smear and a hanging drop were negative. She was instructed to continue basic phenylmercuric nitrate douches daily for one month, at the end of which time smears were again negative. She was discharged and has remained well for fifteen months.

Of the 13 dispensary cases, 6 had previous therapy directed against the *T. vaginalis*. These included the 2 cases mentioned in a previous report.¹² This therapy consisted in the use of hexylresorcinol, acriflavine, potassium permanganate, picric acid, merthiolate, and powdered quinine. These cases were then treated with basic phenylmercuric nitrate as outlined. Three made what appeared to be complete recoveries in three and a half to six months and have remained negative since June, 1934. Three cases showed similar early results. One patient remained away after one month's treatment and returned six months later with either an exacerbation or a reinfection. She cleared up after three months of intensive treatment. The other 2 cases remained negative for three and five months respectively and returned with reinfections. Return to therapy plus proper cleanliness after bowel movement has cured both patients. The 7 dispensary cases having no previous therapy made the most rapid clinical and microscopic recovery. The earliest occurred in seven weeks, the longest in four months.

Besides the factor of cleanliness following defaecation which plays so important a part in the treatment of trichomonas infection, there is another problem

in this connexion which should be stressed. It has been said that the menstrual period, during which time medication is rarely if ever used directly in the vagina, nullifies any therapeutic measures used during the preceding two weeks. If this is true, it may account for the unusual delay encountered in the cure of some of these patients. It has been suggested that in certain selected cases an attempt be made to treat them daily through the menstrual period at least with gentle douches.

ENDOCERVICITIS

In this group there were 14 cases from dispensary practice equally divided as to specific and non-specific infections, and 15 cases from private practice. In the latter group 11 were gonococcal and 4 non-specific.

The most spectacular results were in the group of patients having gonococcal endocervicitis. There appears to be no difference according to whether these patients are dispensary visitants or able to pay for private medical care. Of the total of 18 cases of specific gonococcal endocervicitis treated, not one failed to show a definite improvement on her second visit, usually one week later. All vouchsafed the information that the discharge had lessened and that they "felt better." As in the group discussed in my preliminary report,¹² the discharge had changed from the "thick, greenish-yellow, foul-smelling leucorrhœa to a milk-white, odourless and comparatively thin secretion." All these patients had the benefit of the daily douche with basic phenylmercuric nitrate and showed the results of it in the rapidity with which they became symptom-free. As previously reported, adjuvant treatment in the form of the actual cautery, silver nitrate, and the like for associated erosions, nabothian follicle cysts, &c., could be initiated at an earlier period in the course of treatment than heretofore.

In the group of 11 cases of non-specific endocervicitis (7 in dispensary and 4 in private practice) all showed a rapid amelioration of their symptoms. As a cleansing germicidal douche, basic phenylmercuric nitrate proved its efficacy in this as well as in the other types of infection in the lower female genital tract. As soon as the subjective symptoms had improved and there was a decided change in colour and lessening in the leucorrhœa, adjuvant treatment was successfully employed in each case.

OTHER CONDITIONS

In one case of a *paracervical sinus* following cauterisation, basic phenylmercuric nitrate was used with beneficial results:—

This 38-year-old patient came to the dispensary on May 20th, 1933. A blind paracervical sinus was found parallel to and to the right of the cervical canal, admitting a probe for a distance of 2 cm. She had been treated with various other antiseptics and finally with increasing concentrations of silver nitrate in order to obliterate the sinus, with no results. On Oct. 25th basic phenylmercuric nitrate 1:1500 was instilled into the cervix and the sinus. The patient was instructed to use basic phenylmercuric nitrate daily as a douche. On Nov. 8th the discharge had changed in colour from a greenish-yellow to a milk-white, and in consistency from a tenacious mucoid to a watery type. The patient, who had been much annoyed for several months by the persistent discharge, volunteered the information that for the "first time in ages" she felt better and had no discharge. Examination one week later on the 15th showed a reduction in the depth of the sinus of about one-half. On Dec. 1st, 1933, the patient

was discharged from the dispensary with the sinus completely occluded and the secondary infection associated with her endocervicitis completely eliminated.

Since publication in my preliminary report¹² of the original case of *rectovaginal fistula* which closed spontaneously under the influence of basic phenylmercuric nitrate, a second case of post-operative rectovaginal fistula has been treated in the same way in the out-patient department at Mount Sinai Hospital:—

The patient, aged 33, was referred to the gynaecological dispensary on Oct. 24th, 1934, with the diagnosis of a post-operative rectovaginal fistula following perineorrhaphy. She complained of the passage of small quantities of feces via the vagina, and of a foul vaginal discharge. Examination revealed a foul greenish-yellow discharge coming from the vagina and a fecal discharge from a fistulous opening one-quarter inch in diameter, half an inch behind the introitus. The entire vagina and cervix were thoroughly cleaned with cotton pellets moistened with water. Basic phenylmercuric nitrate 1:1500 was instilled into the cervix and about 5 c.cm. was allowed to remain in the vagina. The patient was advised to use the 1:25,000 basic phenylmercuric nitrate douche twice daily. At the end of the first week the whole vagina looked clean. The fistulous opening into the rectum was clearly visible. The treatment was continued for another week; at the end of this time the edges of the fistulous tract were touched up with 20 per cent. silver nitrate. The douches were continued once instead of twice daily. On Dec. 5th, 1934, the fistula was closed and the patient was instructed to continue the daily douches for several more weeks. On Jan. 2nd, 1935, she was discharged from the gynaecological service completely cured with closure of the fistula and the absence of leucorrhœa.

Post-operative slough.—A woman, aged 46, was admitted to the out-patient department on Feb. 8th, 1935, after a vaginal hysterectomy, right salpingo-oophorectomy and a perineorrhaphy. She complained of a foul, thick, fecal-like discharge which showed no signs of clearing up.

Inspection revealed a large slough high in the vault along the suture line. It appeared at first as if a rectovaginal fistula had occurred. However, upon the removal of the debris and the thick, mucoid, foul-smelling, brownish-yellow discharge, no opening into the rectum could be found. The vagina was cleansed and swabbed with solution of basic phenylmercuric nitrate and the patient was instructed to take the antiseptic douches twice daily. At the end of the first week the improvement was marked. The intervals between douches were gradually lengthened, and at the end of four weeks the patient was discharged as well with absence of any leucorrhœa or slough.

Tinea cruris.—In private practice I had one patient who had had a tinea cruris of long standing. Pelvic examination was negative. There was no leucorrhœa. The tinea involved both thighs in the region of the perineal crural fold and on one side extended to the labium majus. Twice daily applications of basic phenylmercuric nitrate ointment 1:1500 according to the method advocated by Levine¹⁵ cured the tinea in three weeks with no recurrence after six months.

SUMMARY AND CONCLUSIONS

1. Laboratory investigations on the utility of phenylmercuric salts, in particular basic phenylmercuric nitrate, indicate that these compounds combine with the highest bactericidal and fungicidal potency yet discovered for any class of compounds, a relatively low toxicity for animals and for man. The chemical and physical properties of these salts, most of them being colourless, odourless, tasteless, relatively non-irritant, non-corrosive to surgical

instruments, and quite stable, greatly enhance their usefulness.

2. Clinical studies with basic phenylmercuric nitrate, which include up to the present many hundreds of cases in which the compound has been used with excellent results, indicate that this preparation is of great utility in the treatment of a wide variety of infections due to bacteria and fungi. Infections with the protozoon *T. vaginalis* also yield to therapy with basic phenylmercuric nitrate.

THE TREATMENT OF CARCINOMA OF THE LOWER END OF THE ŒSOPHAGUS *

BY ROBERT MAILER, M.D., F.R.C.S. Edin.,
M.S. Minnesota

ASSISTANT SURGEON TO THE VICTORIA INFIRMARY, GLASGOW

CARCINOMA of the œsophagus constitutes between 2½ and 5 per cent. of all cases of malignant disease. There are three definite pathological types:

(1) The bulky, polypoid type of growth which extends into the lumen of the œsophagus causing obstructive symptoms at an early stage.

(2) The shallow ulcerating type causing early symptoms of mediastinal involvement such as pain and backache. Metastases and obstructive symptoms may be absent.

(3) The hard infiltrating scirrhus type which invades the œsophageal wall, encircles the lumen, causes fixation of the walls, and produces obstruction.

The disease is commonest in the lower third of the œsophagus (50 per cent.), and in four cases out of five it is a squamous epithelioma. It is stated that it remains local for quite a long period and that metastases are relatively late, but this is open to question. Abel,¹ in post-mortem examinations of patients dead of œsophageal carcinoma, found 46 to 72 per cent. free from metastases; lymph-nodes, however, were involved in about half the cases. Death is due most commonly to perforation of the œsophagus with the development of pneumonia, mediastinitis, or hæmorrhage, but sometimes there is extension by the blood stream with widespread metastases.

From time to time surgeons have attempted to solve the baffling problem of malignant disease of the gullet but with very little success. The record of

* Based on a communication to the Royal Medico-Chirurgical Society, Glasgow, on April 5th, 1935.

achievement in the field of radical surgery can be summed up in the three cases operated upon by Torek,² Eggers,³ and more recently Grey Turner.⁴ In point of fact the technical difficulties are so great, the disease so well established when first diagnosed, and the condition of the patient so poor, that only in a very exceptional case could success be hoped for, and then only in the hands of a surgeon with the special experience necessary to carry through the highly complicated and difficult operations involved. For this reason surgeons have mostly been content with palliative measures.

Formerly patients showing complete obstruction were submitted to gastrostomy. This operation staved off starvation, and by allowing rest to the œsophagus, relieved the associated inflammatory congestion so that some temporary improvement in swallowing might be expected. Not infrequently, however, the operation seemed to improve the patient's condition but little. Its performance, no doubt, confirmed his worst fears as to the nature of the disease, and with the loss of the mental tonic of being able to swallow food, an attitude of depression and despair was engendered which made the downward trend still more rapid.

It was not unnatural, therefore, that with increasing experience of the œsophagoscope in the diagnosis and treatment of conditions of the gullet, surgeons turned hopefully to a method which appeared to obviate the necessity for a gastrostomy.

TREATMENT BY RADIATION

In view of the success attending the radium treatment of epidermoid carcinoma elsewhere in the body, it was thought that good results should be obtainable in carcinoma of the œsophagus provided the difficulties of approach could be overcome and the technique of exposure accurately worked out. This method was proposed as early as 1904, and soon there were many accounts of apparatus, dosages, filters, and new methods for accurately placing the radium in the œsophagus. There were, however, no reports of cures or even successful palliation and the method fell somewhat into disfavour. Within recent years the most hopeful results have been reported by Guisez,⁵ who has had a very extensive experience of œsophageal work. He used 100 to 120 mg. of radium bromide screened by 1.5 mm. of platinum, inserted every two days for 10 to 12 hours. About six treatments in all were given. Of 270 patients treated in this way, 30 lived for more than 18 months, and of these, one survived 11 years, one 10 years, and one 5 years. On the other hand, Watson,⁶ of the Memorial Hospital, New York, states that none of his cases treated by intra-œsophageal radiation has lived long enough to encourage him to continue with this method.

Direct implantation of radon seeds into the tumour through the œsophagoscope has been given a trial, but it is obvious that with narrowing of the lumen by the growth, uniform distribution of the seeds is difficult to attain. In some cases a Souttar's tube has been used, the tube acting as a carrier for the radon applicator, while in other cases a vulcanite tube of the Symonds's type, with grooves on the wall for carrying radium needles, has been employed.

Surgical exposure of the œsophagus from the outside with implantation of radium round the growth has been tried, but it is too soon to indicate what success is attending this form of treatment. Lastly, high voltage X rays, administered through several portals, has given encouraging results in the hands

of Levitt,⁶ who reported six cases at a meeting of the Royal Society of Medicine last year. It is, however, in carcinoma of the upper end of the œsophagus that X rays are most effective.

On the whole, the results from treatment by radiation have been disappointing. Many different methods have been employed with no permanent cures, and it is still undecided whether the barrier to effective treatment lies in the character of the growth, or whether the difficulties of approach have delayed the finding of the best radiation technique.

EARLIER EXPERIENCES WITH RADIUM THERAPY

Some seven or eight years ago, in an endeavour to improve the outlook in cases of complete malignant obstruction of the lower end of the œsophagus, I adopted the method of opening the stomach, dilating the lower end of the œsophagus with the finger, and introducing a catheter containing radium in contact with the growth, the other end being brought out through the gastrostomy opening. These were cases in which the stricture was impermeable to manipulation from above through the œsophagoscope. The radium (30 mg.) was left in position for 5-7 days. When treatment was over, a tube was left in the stomach for feeding purposes for three weeks, after which the gastrostomy wound was allowed to close. Twelve patients were treated in this way and the results were encouraging. Relief was provided for periods of 6-18 months, and the majority of the patients were able to swallow till near the end.

This method of treatment had very definite disadvantages. In the first place a general anaesthetic was required, and the opening of the stomach widely enough to allow manipulation of the lower end of the œsophagus was attended with a fair degree of shock which in starved and enfeebled patients could not be ignored. Furthermore, it was conceivable that the forcible dilatation with the finger might cause some splitting of the wall of the œsophagus and allow spread of infection. Three patients died within a week of operation from pneumonia or mediastinitis, and even allowing that these patients were very bad risks, I considered the operative procedure too severe for the average case.

Another drawback was the inability to fraction the dosage of radium, with the result that the patient received the whole of the radium reaction when his physical resources were at their lowest ebb.

The main conclusion arising from a study of these earlier cases and the failure to achieve lasting results from radium therapy was that the average squamous epithelioma of the œsophagus is not a very radio-sensitive tumour, and that it seems almost impossible to deliver a lethal dose to the growth without damaging unduly the normal cells in the vicinity. The work of Coutard⁷ at the Radium Institute in Paris suggests that in dealing with growths of relatively low sensitivity the best results are obtained with repeated small doses of radiation extending perhaps over a period of several weeks. With this fractional technique applied to X ray dosage, Coutard was able to obtain improved results in the treatment of such conditions as malignant glands in the neck and carcinoma of the larynx, which had previously responded poorly to radiation therapy. This method stresses the importance of the integrity of the supporting vasculo-connective tissue.

It seemed, therefore, in the light of present knowledge and experience, that the technique for radium

administration in the case of carcinoma of the oesophagus should embody the following features:—

- (1) It should be easy of performance and carry little or no operative risk.
- (2) It should permit of small doses of radiation being given either daily or every second day with the minimum of discomfort and upset to the patient.
- (3) It should permit of gradual dilatation of the stricture.
- (4) The distance factor should be increased so as to obtain better screening and more uniform radiation to the growth.

THE MANAGEMENT OF A CASE

The preliminary diagnosis is made by fluoroscopic examination, and it is important to define accurately the upper and lower limits of the growth by examination in both the horizontal and vertical positions. This also guards one against treating the oesophageal extension of a carcinoma of the cardiac end of the stomach.

If the patient's condition is fairly good, he is submitted to oesophagoscopy examination, at which time the diagnosis is verified and a portion of the tumour removed for microscopic study. One is tempted at times to forego this step in view of the frail condition of the patient and the slight risk entailed, but it is of paramount importance to determine that the growth is really a squamous epithelioma and not the slower growing adenocarcinoma or even a syphilitic lesion.

Patients unable to swallow anything are prepared with rectal salines and glucose and then have a gastrostomy performed under local anaesthesia. At the end of a week, the rest to the gullet alleviates the superadded spasm and the patient is usually able then to swallow fluids. At this stage he is given fine silk to swallow after the method of Dunham,⁸ who first introduced this procedure in 1903. The swallowing is done slowly, not more than a yard in 24 hours. At the end of 48–72 hours, the gastrostomy tube is removed, and with a small blunt right-angled hook the thread is pulled up from the stomach on to the surface. There is never any difficulty in finding the thread provided it has reached the stomach. A few patients find the silk slightly irritating to swallow and in such cases ordinary fine sewing thread can be substituted, the stronger silk being attached to the oral end of the linen once the other end has been retrieved from the stomach.

Very gradual dilatation of the stricture is then carried out by attaching rubber catheters to the silk and pulling them up through the stricture towards the mouth. A larger calibre catheter is used each day until a size 14 to 16 English passes easily. For the radium treatment either a catheter of this calibre is used to begin with, or a special thick-walled rubber tube with a small metal olivary tip which is perforated to allow the passage of the thread. Thirty milligrammes of radium are used, in the form of 5 mg. needles arranged in tandem, the active length being 4 inches. This allows the radium to project 1 inch above and below the apparent limits of the growth in an average case. The position of the tube is checked by radiography, and daily treatments of 4–6 hours are given. The total treatment extends over 100–130 hours, depending upon distance.

When the radium is not in position the patient is fed by catheter through the gastrostomy opening, and is also allowed fluids by mouth. When the treatment is over, the gastrostomy wound is allowed to close. Patients are subsequently examined after

an interval by radiography and oesophagoscope, and if considerable cicatricial narrowing is taking place, dilatation is carried out with metal-tipped bougies guided over a previously swallowed silk thread. Occasionally a second radium treatment is given at the end of three or four months.

RESULTS AND CONCLUSIONS

The series treated in this manner was small, only 11 cases, and did not include some of the most unfavourable cases which were treated by X rays alone. There were no deaths during operation or while the patients were under treatment. The longest survival was 3½ years; three patients survived from 1½ to 2 years, one for 16 months, and six died within a year.

The patients with the bulky polypoid obstructing growths do best, partly because they are diagnosed a little earlier and partly because they appear to react a little better to radium. The ulcerating non-obstructing growths are not improved by treatment. Very old patients and those extremely debilitated react poorly. In a few cases I have tried to improve the results by giving a course of X ray treatment after intra-oesophageal radium, but without much apparent success. One difficulty encountered was that after an adequate radium treatment the patients could not stand a full course of X rays. At the same time I think a combination of radium and X ray treatment offers the best hope of success. It is impossible with X rays alone to build up an adequate depth dosage to the lower end of the oesophagus, but X rays should prove a useful adjunct in the treatment of outlying extensions of the growth which are insufficiently irradiated by the intraluminal radium.

I am satisfied that the main barrier to effective treatment of carcinoma of the oesophagus lies in the relatively late diagnosis of the disease, and the only moderate radiosensitivity of the average growth. It is unusual to meet with a highly radiosensitive growth which has been diagnosed early, and these hopeful cases constitute under 5 per cent. of the total admitted. In such cases a survival period of at least three years should be obtainable by appropriate treatment. With the remainder, a survival of 12–18 months is the best that can be hoped for at the present time. Nevertheless treatment is well worth while, for the patients are maintained in fair comfort until near the end. In conclusion, I think the results from radium treatment have been slightly improved by fractionating the dosage; but the problem of carcinoma of the oesophagus is still unsolved, and its solution lies beyond any mere modification of technique.
